ABSTRACT

1

2   This study presents an off-line global evaluation of the ISBA-TRIP hydrological model

3   including a two-way flood scheme. The flood dynamics is indeed described through the daily

4   coupling between the ISBA land surface model and the TRIP river routing model including a

5   prognostic flood reservoir. This reservoir fills when the river height exceeds the critical river

6   bankfull height and vice-versa. The flood interacts with the soil hydrology through infiltration

7   and with the overlying atmosphere through precipitation interception and free water surface

8   evaporation. The model is evaluated over a relatively long period (1986-2006) at 1° resolution

9   using the Princeton University 3-hourly atmospheric forcing. Four simulations are performed

10   in order to assess the model sensitivity to the river bankfull height. The evaluation is made

11   against satellite-derived global inundation estimates as well as in situ river discharge

12   observations at 122 gauging stations. First, the results show a reasonable simulation of the

13   global distribution of simulated floodplains when compared to satellite-derived estimates. At

14   basin scale, the comparison reveals some discrepancies, both in terms of climatology and

15   interannual variability, but the results remain acceptable for a simple large-scale model. In

16   addition, the simulated river discharges are improved in term of efficiency scores for more than

17   50% of the 122 stations and deteriorated for 4% only. Two mechanisms mainly explain this

18   positive impact: an increase in evapotranspiration that limits the annual discharge

19   overestimation found when flooding is not taking into account and a smoothed river peak flow

20   when the floodplain storage is significant. Finally, the sensitivity experiments suggest that the

21   river bankfull depth is potentially tunable according to the river discharge scores to control the

22   accuracy of the simulated flooded areas and its related increase in land surface evaporation.

23   Such a tuning could be relevant at least for climate studies in which the spatio-temporal

24   variations in precipitation are generally poorly represented.

2

1. Introduction

The land surface hydrology represents an active component of the climate system (Dirmeyer 2000, 2001; Douville 2003, 2004; Koster et al. 2000, 2002) and is likely to influence the water and energy exchanges at the land surface, the ocean salinity and temperature at the mouth of the largest rivers (Durand et al. 2010), and the climate at least at the regional scale (Gedney et al. 2000; Douville et al. 2000a, b; Molod et al. 2004, Lawrence and Slater 2007, Alkama et al. 2008). These land surface processes are parameterized in Continental Hydrologic Systems (CHSs). CHSs are composed by Land Surface Models (LSMs), which provide realistic lower boundary conditions of temperature and moisture in Atmospheric General Circulation Models (AGCMs), and now generally include River Routing Models (RRMs) which convert the runoff simulated by the LSMs into river discharge in order to transfer the continental fresh water into the oceans and then to close the global hydrological cycle.

At the global scale, many studies have focused on RRMs development (Vörösmarty et al. 1989, Liston et al. 1994, Miller et al. 1994, Hagemann and Dümenil 1998, Oki and Sud 1998, Arora and Boer 1999, Coe 1998, Ducharne et al. 2003). These models are generally based on simple budget equations representing the temporal variations of the water mass stored in each grid cell of a hydrological network determined according to the actual topography. This network is generally derived at coarse resolution (from 0.25° by 25° to 4° by 4°) except Coe's model (1998) that used a 5-minute resolution. The main difference between these simple linear reservoir models is related to the processing of the river flow velocity that can be parameterized as:

47 • constant in space and time (Oki and Sud 1998) or using basin scale uniform transfer

48   coefficients (Ducharne et al. 2003)

49 • constant in time but spatially distributed according to various relationships with the

50   topography (Miller et al. 1994, Hagemann and Dümenil 1998, Coe 1998) or with both the

51   mean annual river flow and the topography (Vörösmarty et al. 1989, Liston et al. 1994)

52 • variable in space and time according to the topography, the river geomorphology and the

53   river water height using the Manning (1891) formula (Arora and Boer 1999, Lucas-Picher

54   et al. 2003, Ngo-Duc et al. 2007, Decharme et al. 2010)

55 Nevertheless, most of these models do not account for inland water bodies (Vörösmarty et al.

56 1989, Liston et al. 1994, Miller et al. 1994, Hagemann and Dümenil 1998, Oki and Sud 1998,

57 Arora and Boer 1999, Ducharne et al. 2003) or consider them as static (Coe 1998) while their

58 evolution and variability have an important impact on the Earth's climate system.

59   Water bodies can be separated in two categories: anthropogenic and natural. Man-made

60 inundated surfaces include reservoirs, rice fields and agricultural irrigation while natural

61 inundated areas are related to river flooding, lakes, large ponds, and wetlands (bog, fen, mire,

62 marshes). They have a strong influence on the annual cycle of river discharges in both tropical

63 and high-latitude areas that emphasize their relevance for water resource management (Coe et

64 al. 2002; Coe et al. 2008; Decharme et al. 2008). They affect the overlaying atmosphere

65 through their relatively high evapo-transpiration that enhances latent versus sensible heat

66 exchange with the atmosphere (Krinner et al. 2003). Finally, through CO_2 and/or methane

67 emissions, surface water bodies, especially wetlands, regulate the biogeochemical cycles that

68 impact the climate evolution. Indeed, they are the world's largest source of methane and a

69 major contributor to its inter-annual variability (Houweling et al. 1999; Matthews 2000;

70 Bousquet et al. 2006, Ringeval et al. 2010) and could have contributed significantly to global

71 warming since pre-industrial time (Shindell et al. 2004). Hence quantifying the distribution and

72 variations of surface water bodies over the global land surface is a key question regarding

73 climate change in terms of hydrological impacts as well as methane emissions (Bousquet et al.

74 2006). Consequently, recent efforts have been made to represent natural inland water surfaces

75 in CHSs. Gedney et al. (2004) used an implicit representation in a LSM without any dedicated

76 surface reservoir in order to estimate the potential feedback of wetland methane emissions on

77 climate change. Other studies have proposed simple explicit parameterizations of flooded areas

78 prescribing the residence time of water into pre-dimensioned reservoirs (Coe 1998; Coe et al.

79 2002; Krinner et al. 2003; Guntner et al. 2007).

80   However, the recent development of new satellite observations and techniques (Alsdorf

81 et al. 2007; Prigent et al. 2001, 2007; Papa et al. 2010a) shows that inland water bodies greatly

82 vary in space and time and evolve with environmental and climate conditions. Some new

83 modeling capabilities have been proposed to represent inland water bodies, or at least

84 floodplains, at continental scale and at fine resolution. Coe et al. (2008) developed a distributed

85 river model at 5-minute resolution over the Amazon River in which the flood processes are

86 parameterized using information from the 1km resolution Shuttle Radar Topography Mission

87 (SRTM) data set. Such fine resolution information provides physically based fractional

88 flooding inundation of grid cells from a statistical representation of sub-grid-scale floodplain

89 morphology. Over the same basin, Beighley et al. (2009) developed a modelling framework

90 based on a flexible height resolution representation of land surface topography and a fluvial

91 transport system that is capable of providing realistic channel and floodplains hydraulic

92 characteristics on a daily time scale. Fan and Miguez-Macho (2010) proposed a simple

93 hydrologic framework applied over North America at 30-second resolution to simulate the

94   wetland and inland water bodies based on dynamic and prognostic groundwater water table

95   depth that can support surface water bodies by maintaining a saturated substrate. Nevertheless,

96   only the wetlands distribution and spatial extent was investigated in this study without the

97   evaluation of their time-tendency or dynamic. At a coarse resolution (1° by 1°), Decharme et

98   al. (2008) developed a coupled LSM-RRM flood scheme over South-America to represent the

99   floodplain dynamics and its impact on continental evapotranspiration and energy budget for

100   large scale applications and climate modeling trough the use of a simple sub-grid topographic

101   relationship between water volume and flooded area. At a similar resolution (0.5° by 0.5°),

102   Dadson et al. (2010) proposed also a coupled LSM-RRM flood scheme over the Niger inland

103   delta region based on sub-grid topographic statistics. In terms of model evaluation, the Coe et

104   al. (2008), Decharme et al. (2008) and Dadson et al. (2010) schemes were the first to be

105   evaluated using conjointly satellite-derived inundation estimates and in-situ river discharge

106   observations whereas in previous studies only the impact of the flood processes on river

107   discharges was investigated (Coe 1998; Krinner et al. 2003; Coe et al. 2002; Guntner et al.

108   2007; Beighley et al. 2009).

109   Focusing on Decharme et al. (2008), the simple river flood scheme attempts to

110   represent the space-time variations of the large seasonal inundations at continental scale, but

111   excluding lakes, large ponds and wetlands. The flood dynamics is described through the daily

112   coupling between the Interaction Sol-Biosphère-Atmosphère (ISBA) LSM (Noilhan and

113   Planton 1989) and the Total Runoff Integrating Pathways (TRIP) RRM (Oki and Sud 1998)

114   including a prognostic flood reservoir added by Decharme et al. (2008). This reservoir fills

115   when the river height exceeds the river bankfull height and vice-versa. Its dimension evolves

116   dynamically according to the flood water mass and the sub-grid topography in a given grid-

117   cell. The reservoir interacts with the soil hydrology through infiltration and with the overlying

6

118 atmosphere through precipitation interception and free water surface evaporation. The
119 evaluation was made in off-line mode over South-America. Results showed that due to a basin-
120 scale increase in surface evaporation, the monthly discharges over the Parana River basin were
121 drastically improved while over the Amazon basin, the improvement on the simulated
122 discharge was mainly related to the introduction of a delay in the timing of river flow through
123 water store in the flooded area. In addition, an acceptable agreement between the simulated
124 flooded areas and satellite-based inundation estimates was also found. These results were
125 similar to that found at finer resolution by Coe et al (2008) over the Amazon.

126   The main objective of the present study is to evaluate and to assess the robustness of
127 this flood scheme at the global scale, an essential step before its use into coupled continent-
128 atmosphere climate studies. This evaluation is done in off-line mode in which the ISBA-TRIP
129 flood model is forced by the global meteorological data set provided by Princeton University
130 (http://hydrology.princeton.edu) on a 3-hourly time step and at 1° resolution (Sheffield et al.
131 2006). As proposed by Coe et al. (2008) and Decharme et al. (2008) but only at regional to
132 continental scale, the model outputs are evaluated against in situ river discharge measurements
133 at 122 gauging stations as well as again satellite-derived inundation estimates from Prigent et
134 al. (2007) now available from 1993 to 2004 (Papa et al., 2010a). This original evaluation
135 strategy for a global scale study permits to evaluate both the floodplain climatology and
136 variability, which is an important issue for possible feedbacks on the climate system, and for
137 the impact of flood events on simulated river discharge and water budget. The ISBA-TRIP
138 flood scheme is presented in section 2. The experimental design, the specific parameters of the
139 floodplain parameterization, and the different data sets are described in section 3. Results are
140 shown in section 4 while a discussion and the main conclusions are provided in sections 5 and
141 6 respectively.

2. The ISBA-TRIP flood model

2.1. Review of ISBA-TRIP

ISBA is a relatively simple LSM that uses the force-restore method to calculate the time evolution of the surface energy and water budgets (Noilhan and Planton 1989). It includes a comprehensive sub-grid hydrology to account for the heterogeneity of precipitation, topography and vegetation in each grid cell. A TOPMODEL approach (Beven and Kirkby, 1979) has been used to simulate a saturated fraction, f_{sat}, where precipitation is entirely converted into surface runoff (Decharme et al. 2006). Infiltration is computed via two sub-grid exponential distributions of rainfall intensity and soil maximum infiltration capacity. Finally, a tile approach is used to represent land cover and soil depth heterogeneities (Decharme and Douville 2006a).

The original TRIP RRM was developed by Oki and Sud (1998) at the University of Tokyo. It was first used at Météo-France to convert the simulated runoff into river discharge using a global river channel network at 1° resolution. In the new ISBA-TRIP CHS (Decharme et al. 2010), TRIP takes into account a simple groundwater reservoir which can be seen as a simple soil-water storage and a variable stream flow velocity as proposed by Arora and Boer (1999). This variable velocity, v (m.s^{-1}), is computed via the Manning's formula:

$$v = \frac{\kappa}{n} R^{2/3} s^{1/2} \qquad (1)$$

where s (m.m^{-1}) is the downstream river height loss per unit length approximated as the river bed slope, R (m) the hydraulic radius, κ (m^{-3}.s^{-1}) a constant equal to 1, and n the dimensionless Manning friction factor which varies from the upstream part to the mouth of each basin (see

163   section 3). The hydraulic radius is related to the stream water depth, h_s (m), calculated from the

164   stream water mass, S (kg), assuming a rectangular river cross-section (Arora and Boer, 1999):

165    $$R = \frac{Wh_s}{W + 2h_s} \quad \text{where} \quad h_s = \frac{S}{LW\rho_w} \qquad (2)$$

166   where ρ_w (kg.m^{-3}) is the water density, W (m) the bankfull river width, and L (m) the river

167   length that takes into account a meandering ratio of 1.4 as proposed by Oki and Sud (1998).

168   TRIP is then based on two prognostic equations for the stream reservoir and the groundwater

169   reservoir, G (kg):

170    $$\left| \begin{aligned} \frac{\partial S}{\partial t} &= Q_{in}^S + \frac{G}{\tau} - \frac{v}{L}S \\ \frac{\partial G}{\partial t} &= Q_{sb} - \frac{G}{\tau} \end{aligned} \right. \qquad (3)$$

171   where Q_{sb} (kg.s^{-1}) is the deep drainage from ISBA, Q_{in}^S (kg.s^{-1}) the sum of the surface runoff

172   from ISBA within the grid cell with the water inflow from the upstream neighboring grid cells,

173   and τ (s) the uniform and constant time delay factor of the groundwater reservoir which is

174   fixed to 30 days. This last reservoir does not represent the groundwater dynamics but only

175   delays the groundwater flow contribution to the surface river reservoir within a particular grid

176   cell: the deep drainage is fed into the surface reservoir with a time delay factor of τ. More

177   details can be found in Decharme et al. (2010).

178   2.2.   The flood scheme

179   As proposed by Decharme et al. (2008), a simple coupling between ISBA and TRIP is

180   proposed and the floodplains are explicitly represented into the surface water and energy

181   budgets computed by ISBA. A floodplain reservoir, F (kg), is added in TRIP that is now based

182   on three prognostic equations:

183

$$\left|\begin{array}{l}\dfrac{\partial S}{\partial t} = Q_{in}^{S} + \dfrac{G}{\tau} - \dfrac{v}{L}S - Q_{in}^{F} + Q_{out}^{F} \\[2mm] \dfrac{\partial G}{\partial t} = Q_{sb} - \dfrac{G}{\tau} \\[2mm] \dfrac{\partial F}{\partial t} = Q_{in}^{F} - Q_{out}^{F} + \left(P_{f} - I_{f} - E_{f}\right)\end{array}\right.$$
(4)

184   where Q_{in}^{F} and Q_{out}^{F} (kg.s^{-1}) represent the flood inflow and outflow respectively, and P_f, I_f and

185   E_f (kg.s^{-1}) the precipitation interception by the floodplains, the re-infiltration and the direct free

186   water surface evaporation estimated by ISBA respectively. I_f occurs if the flooded fraction,

187   f_{flood}, calculated according to the subgrid topography (Appendix A) is superior to the soil

188   saturated fraction, f_{sat}, and depends on the soil maximum infiltration capacity. In other words,

189   the floodplains cannot infiltrate the fraction of the grid-cell for which the soil is saturated. To a

190   first approximation, it allows to simply represent the fact that the actual floodplains evolve

191   according to the presence of shallow aquifer and water table depth variations.

192   As shown in Figure 1a, a simplified rectangular geometry is assumed to represent the

193   cross section between the floodplain and the river reservoirs in each grid cell. River flooding

194   arises when the water height of the stream reservoir is higher than the critical bankfull height,

195   h_c, and the flood outflow and inflow from this reservoir (Equation 4) are given by:

196

$$\left|\begin{array}{l}Q_{in}^{F} = \dfrac{v_{in}}{W + W_{f}} M_{f} \\[3mm] Q_{out}^{F} = \dfrac{v_{out}}{W + W_{f}} min\left(M_{f}, F\right)\end{array}\right.$$
(5)

197   where W_f (m) is the floodplain width (Appendix A), and M_f (kg) the potential inflow (positive

198   M_f) or outflow (negative M_f) assuming an equilibrium state between the stream and the

199   floodplain water depth:

200     $M_{f} = \rho_{w} L_{f} W\left(h_{s} - h_{c} - h_{f}\right)$
(6)

201 where L_f (m) and h_f (m) are the length along the river and the depth of the floodplains, h_s (m)

202 the water height of the stream reservoir, and h_c (m) the critical bankfull river height. $W+W_f$

203 represents the distance covered by M_f from the stream to the floodplains or conversely. v_{in} and

204 v_{out} (m.s^{-1}) are the flood inflow and outflow velocities computed using the Manning's formula:

205
$$v_{in,out} = \frac{s_{in,out}^{1/2}}{n_f} R_{in,out}^{2/3} \qquad (7)$$

206 where n_f is the Manning roughness coefficient for the floodplains that varies according to the

207 vegetation type (section 3) while $s_{in,out}$ (m.m^{-1}) and $R_{in,out}$ (m) are the inflow (or outflow) slope

208 and hydraulic radius respectively at the interface between the floodplain and the river stream.

209 More details can be found in Appendix A. Note that over Greenland, variable flow velocity and

210 floodplains are not activated and a constant flow velocity of 0.5 m.s^{-1} is used.

211 ## 3. Experimental design

212 ### 3.1. TRIP specific parameters

213 As discussed in Decharme et al. (2010), a special attention has been paid to the

214 computation of the river bed slope at 1° by 1° resolution. River bed slope is indeed a critical

215 parameter to compute velocity via the Manning formula (Equation 1). The STN-30p Digital

216 Elevation Model (DEM) provided at 0.5° by 0.5° resolution by the ISLSCP2 database

217 [http://islscp2.sesda.com] has been used. The STN-30p DEM was heavily edited to represent

218 the actual elevation along the river network on a global scale, based on the aggregated

219 HYDRO1K DEM at 1km resolution. Further adjustments were made to eliminate some of the

220 unrealistic rapid slope changes in the STN-30p DEM along the global river network. As

221 described in Decharme et al. (2010), the STN-30p DEM was finely interpolated at 1° by 1°

222 resolution. To sum up, a 1° grid box is composed by four 0.5° grid boxes. If one of the four

223   0.5° grid boxes represents a mountain while the three other correspond to the valley where the

224   major river flows, the interpolation to 1° resolution is only made via the averaging of the three

225   valley's 0.5° grid boxes. This approach permits to compute elevation along the river at 1°

226   resolution and to calculate the river bed slopes with a better accuracy.

227   In this study, the Manning friction factor varies arbitrary from 0.04 near the river mouth

228   to 0.06 in the upstream grid cells. This factor can be defined as "the resistance of the bed of a

229   channel to the flow of water in it". As discussed in Decharme et al (2010), it is difficult to

230   compute at global scale. It generally varies from low values for natural streams with deep pools

231   as the river mouth to higher values for upstream small rivers. Common estimates give values

232   around 0.024-0.075 for natural streams (Barnes 1967). Previous global studies generally used a

233   global constant value of 0.035 (Arora et al. 1999, Arora and Boer 1999, Lucas-Picher et al.

234   2003), which has strong limitations given that the values greatly vary in natural streams. Here,

235   it is assumed that upstream grid cells represented the narrower rivers and that the mouths could

236   be seen as a "natural stream with deep pools" in each basin. As a consequence, a linear

237   relationship is taken between the Manning n and the river stream order, SO, given by TRIP in

238   each grid cell of a given basin:

239     $$n = n_{min} + \left(n_{max} - n_{min}\right)\left(\frac{SO_{max} - SO}{SO_{max} - SO_{min}}\right) \qquad (8)$$

240   where n_{max} and n_{min} are the maximum and the minimum value of the Manning friction factor

241   (respectively equal to 0.06 and 0.04), SO_{min} and SO_{max} the minimum and maximum stream

242   order in each basins of the TRIP network.

243   The river width is an important parameter because it is jointly used in the simulation of

244   the river flow and the floodplain dynamics. It is computed over the whole TRIP network via an

245   empirical mathematical formulation that generally describes a geomorphologic relationship

246 between W and the mean annual discharge at each river cross section (Knighton 1998; Arora

247 and Boer 1999; Moody and Troutman 2002):

248 $$W = max\left(30, \beta \times Q_{yr}^{0.5}\right) \qquad (9)$$

249 where Q_{yr} (m^3/s) is the annual mean discharge in each grid cell estimated using the global

250 runoff database from Cogley (1998). As shown in many studies, the β coefficient can vary

251 drastically from one basin to another (Knighton 1998; Arora and Boer 1999; Moody and

252 Troutman 2002). As for example, using width and discharge observations, Arora et al. (1999)

253 found a value of 32 for the Amazon River while Moody and Troutman (2002) found 17 for the

254 Mississippi River. In this study, β is fixed for five different hydrological regions of the world

255 as shown in Figure 1b. β is 32 for equatorial or sub-tropical basins, 25 for arctic or sub-arctic

256 basins, 20 for "monsoon" basins, 15 for temperate basins, and 13 for semi-arid or arid basins.

257 Each value has been chosen so that the resulting river mouths match the following values:

258 15000m for the Amazon (equatorial), 2000-3000m for arctic rivers, 500-2000m for temperate

259 rivers, 1500-3000m for monsoon rivers, and less than 1000m for semi-arid or arid rivers. The

260 spatial distribution of the river width is given in Figure 1c while some calculated values are

261 given in Table 1.

262   As shown in Decharme et al. (2008) over South-America, the key parameter for the

263 floodplain parameterization is h_c, the critical river bankfull height. In this previous study, h_c

264 was computed via a linear relationship with the river width. Nevertheless, this previous

265 formulation induces a drastic sharp transition in h_c value at the basin boundary, especially in

266 the upstream part of the Amazon. In this study, a non linear function is proposed:

267 $$h_c = W^{1/3} \qquad (10)$$

268   A global distribution of h_c is given in Figure 1d. However, as described in the next section, two

269   additional sensitivity experiments are also done with $h_c\pm25\%$ leading to an increase or a

270   decrease in bankfull height from about 1m to 6m (Table 1).

271   Finally, the Manning roughness coefficient for the floodplains, n_f, is computed by using

272   the spatial distribution of the 12 vegetation types at 1° resolution specified according to the 1-

273   km ECOCLIMAP data base of Météo-France (Masson et al. 2003). Indeed, the vegetation has

274   generally a non-negligible impact on this roughness coefficient (Thomas and Nisbet 2006) and

275   a simple solution is used:

276    $$n_f = \sum_{i=1}^{12}\left(vegt_i \times n_i\right) \tag{11}$$

277   where n_i is the floodplain roughness coefficient corresponding to one vegetation type (Table 2),

278   and $vegt_i$ the grid-cell fraction of each vegetation types. As shown in Figure 2, n_f, is larger in

279   densely vegetated areas and lower for sparser vegetated regions.

280   3.2.   Experiments

281   The experimental design is similar to Decharme et al. (2008). An off-line hydrological

282   simulation with the flood scheme (*FLD*) is compared to a control experiment without

283   floodplains (*CTL*). In addition, two sensitivity experiments to the h_c parameter are also

284   performed globally using $h_c\pm25\%$. These two simulations permit to present a sensitivity study

285   to the h_c parameter. In Decharme et al (2008), a comparable sensitivity experiment to h_c over

286   South-America basins had suggested that the model is relatively robust, without any particular

287   tuning, but such conclusion must be investigated and confirmed at global scale. ISBA and

288   TRIP are integrated at 1° resolution using 30-min and 1h time step respectively over 1983-

289   2006 where the first three years are considered as spin-up. Every day, the total runoff (surface

290   runoff + deep drainage) simulated by ISBA is fed into TRIP which returns to ISBA the grid-

291   cell floodplain fraction and the flooded water mass in order to calculate P_f, I_f, E_f (Equation 4)

292   and the surface energy budget.

293   The global meteorological forcing is provided by Princeton University

294   (http://hydrology.princeton.edu) at a 3-hourly time step and 1° resolution. This data set is based

295   on the National Center of Environmental Prediction-National Center for Atmospheric Research

296   (NCEP-NCAR) reanalysis. Sheffield et al. (2006) carried out corrections of the systematic

297   biases in the 6-hourly NCEP-NCAR reanalyses via hybridization with global monthly gridded

298   observations. In addition, the precipitation was disaggregated in both space and time at 1°

299   resolution via statistical downscaling and at 3-hourly time step using information from the 3-

300   hourly Tropical Rainfall Measuring Mission (TRMM) data set. More details about this forcing

301   product can be found in Sheffield et al. (2006). The 3-hourly precipitation from Sheffield et al.

302   (2006) is hybridized to match the monthly value from the Global Precipitation Climatology

303   Center (GPCC) Full Data Product V4 (http://www.dwd.de). As shown by Decharme and

304   Douville (2006b), the GPCC climatology appears to be a better product to perform global

305   hydrological applications.

306   The land surface parameters used by ISBA are specified according to the 1-km

307   resolution ECOCLIMAP database developed at CNRM (Masson et al. 2003). The soil textural

308   properties are given by the Harmonized World Soil Database of the Food and Agricultural

309   Organization at 1 km resolution (FAO 2009). Vegetation parameters are defined using two

310   vegetation data sets: the Corine Land Cover Archive at 250 m resolution over Europe and from

311   the University of Maryland (Hensen et al. 2000) data set elsewhere at 1 km. All topographic

312   information is specified according to the 30-arcsecond resolution GTOPO30 data set

313   (http://eros.usgs.gov/products/elevation/gtopo30/gtopo30.html) and the 1 km resolution

314   HYDRO1K   product   (Verdin   and   Greenlee   1996;

315   http://eros.usgs.gov/#/Find_Data/Product_and_Data_Available/gtopo30/hydro).

316   3.3.   Evaluation data sets

317   Over the evaluation period (1986-2006), the simulated discharges are compared to

318   gauging measurements from the HyBAm data set (http://www.mpl.ird.fr/hybam/) for the

319   Amazon, the R-ArticNet database (University of New Hampshire; http://www.r-

320   arcticnet.sr.unh.edu/v3.0/index.html) for high latitude basins, the Bangladesh Water

321   Development Board data set for the Ganges as described in Papa et al. (2010b), and elsewhere

322   from the Global Runoff Data Center (GRDC; http://www.grdc.sr.unh.edu/index.html). This

323   evaluation data set combines in total 122 gauging measurements distributed over the globe

324   (Figure 3). Only sub-basins with drainage areas of at least 10^5 km² and with a minimum

325   observed period of four years are kept.

326   In addition, the satellite-derived inundation estimates are used to evaluate the spatial

327   distribution and the time evolution of the simulated flooded areas over the 1993-2004 period

328   (Prigent et al 2007; Papa et al. 2010a). This data set quantifies at the global scale the monthly

329   variations of the distribution of surface water extent at ~25km sampling intervals. As described

330   in detail by Prigent et al (2001, 2007), it is derived from a complementary suite of satellite

331   observations: Normalized Difference Vegetation Index (NDVI) given by the Advanced Very

332   High Resolution Radiometer (AVHRR); active microwave from the European Remote Sensing

333   (ERS-1) scatterometer backscatter at 5.25 GHz; and finally, passive microwave emissivities

334   between estimated from the Special Sensor Microwave/ Imager (SSM/I) by removing the

335   contributions of the atmosphere (water vapor, clouds, rain) and the modulation by the surface

336   temperature, using ancillary data from visible and infra-red satellite observations from the

International Satellite Cloud Climatology Project (ISCCP) and the National Centers for Environmental Prediction (NCEP) reanalysis. Global monthly-mean surface water extent data set is created with a 0.25° spatial resolution at the equator and is currently available from 1993 to 2004 (Prigent et al 2007; Papa et al 2010a). In the present study, this data set is then interpolated at 1° resolution and named hereafter *P07*. The global distribution of the *P07* mean inundated areas from 1993 to 2004 is given in Figure 4a.

Because P07 does not make distinction between the diverse anthropogenic and/or natural water bodies while the ISBA-TRIP output must be compared with floodplain areas only, two additional data sets are used to hybridize *P07* in order to conserve information on flood interannual variability only: the Global Lakes and Wetland Database (GLWD) and the Monthly Irrigated and Rainfed Crop Areas around the year 2000 (MIRCA2000) database. The GLWD data (Lehner and Döll 2004) gives the global distribution of 12 types of surface water bodies as lakes, wetland and floodplains at 30arc second resolution (~1km at the equator). In this study, this product is interpolated at 1° resolution for lake, reservoir, and bog, fen and mire types as shown in Figure 4b as well as for river, floodplain and flooded forest types as shown in Figure 4c. The MIRCA2000 product (Portmann et al. 2010) provides both irrigated and rainfed crop areas of 26 crop classes for each month of a year around the year 2000 at 5arc minute resolution (~9.2km at the equator). This product, which represents the sum of the 26 irrigated crop classes, is also interpolated at a 1° resolution and the global distribution of the annual maximum is given in Figure 4d.

Figure 4 shows that *P07* cannot be directly compared with the simulated floodplain extents because it makes no distinction between floodplains and other surface water bodies. P07 is then hybridized with the GLWD and the MIRCA2000 products to build an alternative product more comparable with the model simulations. This hybridization is carried out

361   following two steps. First, the GLWD lakes, and bogs, fens and mires areas, L_{GLWD}, as well as

362   the MIRCA2000 annual cycle I_{mth}, are subtracted from $P07$ where the GLWD rivers,

363   floodplains and intermittent lake/floodplain areas, F_{GLWD}, exist:

364    $$P_{07/GM}(t) = \delta \times max[0, P07(t) - L_{GLWD} - I_{mth}] \quad \begin{vmatrix} \delta = 1 & \forall F_{GLWD} > 0 \\ \delta = 0 & \forall F_{GLWD} = 0 \end{vmatrix} \quad (12)$$

365   where t (month) is the time and $P_{07/GM}$ the new final product.

366   4. **Results**

367   4.1.   Flooded area

368   Figure 5 shows the comparison between the mean annual cycles of both the $P_{07/GM}$

369   inundated areas and the simulated *FLD* floodplains. For each season, the global distribution of

370   the floodplains simulated by *FLD* appears robust even if the simulated flooded areas seem to

371   be underestimated especially over South Asia and Northern Canada. The comparison of *FLD*

372   with the two sensitivity experiments ($h_c \pm 25\%$), based on the 1993-2004 mean flooded areas

373   and given in Figure 6, underlines the impact of the river bankfull height on the simulated

374   flooded areas. As expected, a lower h_c induces larger floodplains and inversely. Following

375   Equation 6, if h_c decreases (increases), the potential inflow into the floodplain reservoir

376   increases (decreases) according to Equation 6, and then the resulting flooded areas also

377   increase (decrease). Note that $h_c+25\%$ drastically underestimates $P_{07/GM}$ globally while $h_c-25\%$

378   is in better agreement except over Europe and Russia where the flooded areas appear too

379   dense.

380   Figure 7 shows the basin-averaged annual cycles of monthly floodplain fractions. Over

381   the Arctic basins (Mackenzie, Ob, Lena), the main difference between *P07* and $P_{07/GM}$ is linked

382   to the important density of lakes, especially over the Mackenzie basin, and bogs, fens and

383   mires elsewhere (Figure 4b). The flooded areas are smaller over East Siberia (Lena) than over

384   the Ob and/or Mackenzie basins, and generally located near the river stream (Figure 6a). At

385   these high latitudes, according to Figure 5, the *FLD* simulated flooded area seems to be

386   underestimated, especially during summer (June-July-August). In addition, the simulated

387   flooded area starts earlier than the satellite-derived estimates. Over Central and/or Eastern

388   Europe basins, the main difference between *P07* and $P_{07/GM}$ is linked to the presence of lakes

389   and reservoirs over the Volga basin and irrigation over the Danube. Over the Volga basin, the

390   *FLD* simulated flooded areas are overestimated during spring but the mean annual cycle is in

391   agreement with satellite-based estimates. The same behaviour is observed over the Danube

392   with larger differences but still in the $P07/P_{07/GM}$ estimated range. Over North America

393   (Mississippi), the main $P07/P_{07/GM}$ difference is due to irrigation and the Mississippi simulated

394   flooded fractions are relatively consistent with $P_{07/GM}$. Over Africa (Congo, Niger), a small

395   fraction of lakes explains the $P07/P_{07/GM}$ difference. The Congo basin exhibits small floodplain

396   areas and *FLD* is slightly underestimated. Over the Niger, while the amplitude of the simulated

397   annual cycle appears acceptable, the *FLD* flooded areas start later and shows a too long

398   persistence of the flooding season. Over South America (Amazon, Parana), the small

399    $P07/P_{07/GM}$ difference is linked to the presence of lakes. The *FLD* simulated floodplains are

400   generally underestimated. Over South Asia (Ganges, Mekong), the $P07/P_{07/GM}$ difference is

401   mainly due to intensive irrigation. The *FLD* simulated floodplains are poorly reproduced with a

402   clear underestimation and a flooded season that starts too late (~2-3 months later). Some

403   explanations will be given in the discussion section. Regarding the sensitivity of h_c, the

404   difference between *FLD* and $h_c\pm25\%$ appears non-negligible everywhere. According to Figure

405   6 and despite the general poor results over South Asia, $h_c+25\%$ accentuates the *FLD*

406   underestimation while $h_c-25\%$ attempts to generally overestimate the simulated flooded areas

407   except over the Mackenzie, the Mississippi, the Congo and the Parana where the simulated

408   annual cycles seem to be better reproduced.

409   Moving to inter-annual variability, Figure 8 shows the basin-averaged anomalies of the

410   floodplain extent for $P_{07/GM}$, *FLD* and $h_c\pm25\%$. The correlation and Root Mean Square Error

411   (RMSE) for each experiment are also given. Generally speaking, the monthly anomalies are

412   reasonably reproduced by *FLD*, especially over the Ob, Mississippi, Congo, Niger, Parana and

413   Mekong basins even if these results cannot be considered satisfactory due to some poor

414   correlation scores. The simulated flooded areas are smoothed when h_c increases ($h_c+25\%$) and

415   then the RMSE scores are generally improved to the detriment of the monthly correlations. The

416   main exception is observed over Siberia (Ob, Lena) where all scores are improved. Conversely,

417   a decrease in h_c (h_c-25%) increases the signal variability and then favors the correlations to the

418   detriment of RMSE scores. Nevertheless, over all basins the sensitivity of h_c remains generally

419   relatively weak compared to the model error.

420   4.2.   River discharges

421   It is now well known that seasonal flooding affects the river flow in many regions of

422   the world from tropical to high latitude basins. Without the parameterization of flooding and

423   their variations, CHSs tend to drastically overestimate Tropical and/or West African river

424   discharges, which can be mainly related to the non representation of direct evaporation from

425   free surface water bodies (Ngo-Duc et al. 2005; Decharme and Douville 2007, Decharme et al.

426   2008, Alkama et al. 2010). Over Arctic basins and especially the Ob and Mackenzie Rivers,

427   large floods occur in May/June when the mass of water in the river increases due to snow

428   melting. Consequently, a significant part of the water is not available for flowing and flooding

429   limits the stream flow velocity compared to basins with more negligible floodplain processes

430   (Yenisey, Lena). For example, over the Ob, large floods appear after the snowmelt period and

431   can cover an important part of the basin, especially at the confluence of the Ob and the Irtysh

432   (Figure 5 and 7). The observed flow velocity is generally limited to 0.5 m.s^{-1} due to the

433   significant amount of water stored in these large floodplains (Kouraev at al. 2004, Frappart et

434   al. 2010) whereas without flooding, this velocity can be drastically faster and can reach 1 m.s^{-1}

435   to 2 m.s^{-1} (Arora and Boer 1999, Decharme et al. 2010). Such processes that delay and

436   attenuate the peak discharge during large floodplain storage are also dominant over the

437   Amazon basin (Coe 2008, Decharme et al. 2008).

438   In this section, the simulated river discharges with (*FLD*) and without (*CTL*) flooding

439   are now compared to gauging measurements. The present evaluation stage is important for

440   hydrological applications as well as for future climate studies. Beside the direct evaluation of

441   the simulated discharge scores, it permits to assess the interaction between the floodplains and

442   the river flow as well as to evaluate indirectly the ISBA-TRIP water budget. This evaluation is

443   done with the help of the most popular skill scores used in hydrology. These scores are: the

444   annual discharge ratio criterion ($Ratio = \overline{Q_{sim}} / \overline{Q_{obs}}$), the RMSE, and the efficiency (*Eff*) (Nash

445   and Sutcliffe, 1970) criterion that measures the model ability to capture the monthly discharge

446   dynamics. This last skill score is defined as follows:

447    $$Eff = 1.0 - \frac{\sum (Q_{sim}(t) - Q_{obs}(t))^2}{\sum (Q_{obs}(t) - \overline{Q_{obs}})^2}$$ (13)

448   where $\overline{Q_{obs}}$ represents the observed temporal mean. *Eff* can be negative if the simulated

449   discharge is very poor and is above 0.5 for a reasonable simulation.

450   Figure 9 shows the global distribution of the difference between the *CTL* and *FLD*

451   discharges in terms of annual ratio, efficiency, and monthly anomaly RMSE. The annual ratio

452 is reduced (*FLD-CTL ratio* difference inferior to -0.05 in Figure 9b) over 35% of the 122

453 gauging stations and mainly where this annual ratio is superior to 1.3 (25% of all stations). As

454 it will be shown later, this decrease in annual discharge is related to the increase in continental

455 evapo-transpiration via the direct evaporation of the floodplains. The efficiency scores are

456 increased (*Eff* difference superior to 0.05 in Figure 9d) over 50% of all stations and only

457 reduced (*Eff* difference inferior to -0.05) for 5 stations. The monthly anomaly RMSE scores are

458 also improved (RMSE difference inferior to -0.01 in Figure 9f) over 50% of all stations and

459 only deteriorated (RMSE difference superior to 0.01) for 4 stations. In other words, *FLD*

460 reduces the annual ratio especially over the stations where the *CTL* discharge overestimations

461 are the largest (Figure 9a). This fact is particularly relevant over Africa, Australia, and South

462 America. As discussed before, over these regions this decrease in simulating river discharges is

463 mainly responsible to the general positive impact on both the efficiency scores (Figure 9d) and

464 the monthly anomalies RMSE (Figure 9f). Elsewhere, when an improvement is found, it is

465 mainly due to a weaker peak in the river flow related to the floodplain storage. Conversely,

466 some score deteriorations appear over Eastern Siberia (Lena, Amur) and near the mouth of the

467 Mississippi River where the flooded areas are the largest (Figure 6a and b). As shown in Figure

468 9a, the Lena (or Amur) River discharges are clearly underestimated by *CTL*. So, even if *FLD*

469 induces a slight decrease in river discharges, this decrease is sufficient to impact the efficiency

470 scores. Over the Mississippi, the simulated floodplains seem to be too important at least near

471 the downstream part of the basin.

472   As shown in Figure 10 which represents the global distribution of the h_c sensitivity on

473 the simulated river discharges in terms of efficiency and monthly anomalies RMSE, an

474 increase in h_c and then a decrease in simulated flooded areas (Figure 5c) improve these skill

475 scores (+0.15 for *Eff* and -0.02 for RMSE) near the mouth of the Mississippi basin (Figures 10a

22

476 and 10c). Conversely, a decrease in h_c and then an increase in simulated flooded areas (Figure

477 5d) attempt to improve the scores over many regions of the globe. Exceptions are found over

478 Siberia, the Amazon, South Europe, a part of South Asia and accordingly the downstream part

479 of the Mississippi basin. The efficiency scores are increased (h_c-25%-FLD Eff difference

480 superior to 0.05 in Figure 10b) over 45% of all stations and only reduced (*Eff* difference

481 inferior to -0.05) over 15%. The monthly anomaly RMSE scores are also improved (RMSE

482 difference inferior to -0.01 in Figure 10d) over 30% of all stations and only deteriorated

483 (RMSE difference superior to 0.01) over 10%. These results underline the non-negligible

484 impact of the h_c value on the quality of the simulated discharges.

485 Focusing on the downstream station of the major world river basins, Figure 11

486 compares the mean annual cycle of the simulated and observed discharges. The skill scores

487 given on each plot are calculated over the actual signal and the entire period, and not over the

488 annual cycle. The comparison between *FLD* and *CTL* confirms the general improvement of the

489 simulated discharges pointed out by Figure 9 with the use of the flood scheme. Over the Volga,

490 the Danube, the Parana, the Niger and, to a lesser extent, the Congo River basin, this

491 improvement is mainly related to a decrease in annual discharge ratio. This process is also

492 relevant over the Mackenzie, the Ob or the Amazon basins but the improvement is mainly due

493 to a better simulation of the river flow peak as already discussed. Exceptions are found over the

494 Lena and the Mississippi, and to a lesser extent over the Ganges and the Mekong basins. Over

495 the Lena, as already said, the simulated streamflow is clearly underestimated and a slight

496 decrease in river discharges (due to simulated floodplains) is sufficient to impact the skill

497 scores independently of the value of h_c. However, over the Lena, the Ganges and the Mekong

498 basins the *FLD* simulation remains acceptable with regards to the *CTL* model errors. For

499 example over the Ganges basin, while the annual peak of discharge is more consistent in *FLD*

than in *CTL*, *FLD* conserves the general weakness found in *CTL* where the high discharge season starts later and remains longer than in the observed discharges. This result is in agreement with the same drawback found in simulated floodplain extent (Figure 7). The good scores given by the h_c+25% simulation compared to the others over the Mississippi basin confirm that the simulated flooded areas are too large near its downstream part. Finally, Figure 11 confirms that a decrease in h_c and then an increase in simulated flooded areas can improve the quality of the simulated discharges over many rivers of the globe. Over non-improved basins (Siberian rivers, Danube, Mississippi, Amazon and Ganges), the decrease in h_c induces too large floodplains and then smoother and unrealistic simulated annual cycle.

Moving to the discharge inter-annual variability, Figure 12 shows the comparison between the simulated and observed discharges over the same gauging stations than in Figure 11. The RMSE and correlation of each simulation are also given. In general, *FLD* improves these scores and then the simulated inter-annual variability, which confirms results given in Figure 9f. The main impacts are found over the Arctic basins (Ob, Mackenzie), South America (Amazon, Parana) and West Africa (Niger) even if the correlation is reduced. No significant change is observed over the Danube and South Asian basins, and except over the Mississippi basin, a slight improvement is found elsewhere. Regarding the sensitivity of h_c, beside some exceptions (Ob, Mississippi, Parana, Ganges) where one of the three floodplain simulations is clearly better than the others, the monthly discharges anomalies are generally not impacted by the value of h_c.

4.3.   Water budget

The implementation of the flood scheme leads to a clear reduction in the simulated river discharges (from 5% to 20% compared to *CTL*) over some large river basins (Ob, Mackenzie,

523   Volga, Mississippi, Parana, Niger, and Ganges), while others remain relatively unchanged (less

524   than 5% compared to *CTL*). This reduction in river discharges is logically balanced by an

525   increase in evapo-transpiration. Figure 13 compares the mean annual cycle of the *FLD*

526   simulated evapo-transpiration with *CTL*. The global surface evaporation increase is around 2%

527   and is especially important during spring (March, April, and May). Despite the fact that this

528   increase can appear negligible in some cases, it can also be very important over some regions

529   (North Canada, East Europe, West Siberia, South America or South Africa) as shown in Figure

530   13. Regarding the sensitivity of h_c, the global surface evaporation increase is around 1% for

531    $h_c+25\%$ and 4% for $h_c-25\%$, and it is also more important during spring. The fact that a

532   decrease in h_c induces a strong increase in evaporation is linked to the overestimation of the

533   simulated flooded areas over West Siberia and Europe with $h_c-25\%$ (Figure 6d). With regards

534   to these global values, the sensitivity of h_c is also non-negligible on the land surface water

535   budget.

536   5. **Discussion**

537   The results suggest that the proposed simple flood scheme generally provides a

538   reasonable estimation of the spatio-temporal variability of the flooded areas. In addition, it

539   improves the simulated river discharge over 50% of the 122 gauging stations while it

540   deteriorates the skill score over only 4% of the cases. Elsewhere, the flood scheme has

541   logically no impact because flood processes do not take place over all basins of the world.

542   However, it must be recognized that the basin-scale comparison with satellite-derived flooded

543   area estimates is not very impressive. As pointed out in the introduction, this study is the first

544   attempt to evaluate a simple global two-way flood scheme developed at a coarse resolution

545   where the flood process affects both the surface hydrology (floodplains and river flow) and the

25

546   continental water and energy budgets. Such global work represents another step toward the

547   physical representation of all inland water bodies in climate models. It is interesting to note

548   that the results of Coe et al. (2008) over the Amazon basin, calculated with a finer resolution

549   model, are coherent with this study and confirm the difficulties to accurately simulate together

550   the floodplains and the discharge dynamics.

551   Some deficiencies appear throughout this evaluation. The simulated floodplains are

552   generally underestimated and over some basins (Africa, South-Asia, Pantanal) the discharges

553   remain drastically overestimated. It can be partially due to uncertainties in the precipitation

554   forcing with regards to the small density of GPCC rain gauges in these regions (Decharme and

555   Douville 2006b). Other causes can be related to some important processes not represented in

556   ISBA-TRIP. The man-made irrigation (especially over South Asia) and/or dams can alter the

557   river flow and increase the continental evapo-transpiration (Sacks et al. 2009). Deep and large

558   aquifers relatively uncoupled to the river over arid or semi-arid basins, such as the Niger,

559   contribute to limit the drainage inflow to the river (Leduc et al. 1997 and 2001). Conversely,

560   shallow aquifers support and feed surface water bodies when the water table depth reaches the

561   surface (Fan and Miguez-Macho 2010). In ISBA, the water table depth evolution is simply

562   parameterized thought a TOPMODEL approach. In TRIP, the deep reservoir does not represent

563   the groundwater dynamics but only delays the groundwater flow contribution to the surface

564   river reservoir within a particular grid cell. As a consequence, dynamical aquifer processes are

565   not represented in this study. This fact may partly explain the general underestimation of the

566   simulated floodplains.

567   Over the West Siberian basins, the well known precipitation bias in the GPCC data

568   (Decharme and Douville 2006b) induces a general underestimation of both simulated flooded

569   areas and discharges that does not permit to evaluate the scheme correctly. However, such

26

570 underestimation could be also attributable to the presence of deep permafrost not represented in
571 ISBA in which only the superficial soil ice (from 20 to 35 cm depth) related to the maximum
572 penetration depth of the thermal diurnal wave (Bonne et al. 2000) is parameterized. The
573 permafrost prevents deep drainage and favors the formation of surface water bodies (wetlands,
574 lakes…). This accumulation of surface water can also contribute to feed the floodplains
575 (Kouraev at al. 2004; Price et al. 2005). In addition, all simulations over the Arctic basins show
576 that the simulated flood starts earlier than the satellite-derived ones (Figure 7). Over these
577 regions, the floodplains and river discharges are fed mainly by the springtime snowmelt (Papa
578 et al. 2007, 2008). Considering that the simulated and observed discharges are in phase (Figure
579 11), the fact that the floodplains appear earlier in ISBA-TRIP is likely not due to an earliness
580 of the snowmelt timing simulated by ISBA. As shown by Alkama et al. (2010) with the same
581 configuration of the ISBA-TRIP model and the same atmospheric forcing than in the present
582 study, the simulated snowmelt timing was well reproduced when compared to the National
583 Snow and Ice Data Center (NSIDC; http://nsidc.org/) data. However, in these regions, P07
584 results might be questionable. Because the microwave measurements are sensitive to the snow
585 cover, a snow and ice mask based on the same NSIDC data is applied over the Northern
586 Hemisphere to avoid confusion between snow cover and snow-free pixels (Papa et al. 2007 and
587 2008). An overestimated snow mask might impact the satellite-derived estimates and could be
588 the cause of this slight difference.

589 The main model deficiencies appear over South Asia (Ganges, Mekong) where the
590 simulated floodplains are drastically underestimated even compared to $P_{07/GM}$ in which the
591 significant irrigated areas have been removed to $P07$. This rice irrigation is intensive after the
592 monsoon season, from the end of September to December (Sacks et al. 2009; Portmann et al.
593 2010). Consequently, the fact that $P_{07/GM}$ shows important inunded areas throughout the year

594   is relatively surprising, especially over the Indochina peninsula (Mekong) and at the

595   confluence of the Ganges-Brahmaputra rivers: in these regions, the multi-satellite method

596   might encounter some difficulties in accurately discriminating between very saturated moist

597   soil and standing open water and might overestimate the actual fraction of inundation (Papa et

598   al., 2010a). In addition, hydrological processes in Bangladesh are complicated by the large

599   delta at the confluence of the Ganges and Brahamaputra rivers, which is well captured by

600   satellite (Figure 4a, c and 6a), but not represented by the model. Conversely, the simulated

601   discharges are clearly overestimated after the monsoon season (October to December). This

602   weakness is not due to the flood scheme because the control experiment exhibits the same

603   behavior. It might be rather linked to the intensive rice irrigation that induces large water

604   pumping from the river or aquifers during this period (Sacks et al. 2009; Rodell et al. 2009;

605   Portmann et al. 2010).

606   Conversely to Decharme et al. (2008), the experiments with different values of the river

607   bankfull height reveal that the sensitivity of the model is not negligible over many regions of

608   the globe. Note however that the h_c range (*±25%*) chosen in this study is larger than in

609   Decharme et al. (2008). To sum up, the river bankfull height impacts the land surface

610   evaporation, at least at regional scale, and the range of the increase in evaporation due to the

611   presence of flooded area can be more or less intensive according to the h_c values. An increase

612   in h_c induces a decrease in simulated flooded areas that is not robust compared to the satellite-

613   based estimates and globally deteriorates the simulated river discharge scores compared to

614   *FLD*. The main exception appears over the downstream part of the Mississippi basin where an

615   increase in h_c allows better results. Conversely, a decrease in h_c, which induces an increase in

616   simulated flooded areas, is more robust compared to the satellite-based estimates and discharge

617   measurement. Compared to *FLD*, the efficiency scores are improved over 45% of all stations

618   and only reduced over 15%. This improvement in river discharges score is found especially

619   over North America (excluding the downstream part of the Mississippi basin), South America

620   (excluding the Amazon basin), Africa, Australia, and some basins over Eastern Europe (e.g.

621   Volga) and South Asia (Figure 10b and d). In other words, while h_c could be increased over the

622   Mississippi basin, it also could be decreased over these other regions to improve the model

623   simulations.

624   This tuning should be based mainly on the river discharge scores, given the large

625   distribution of river gauging measurements over the globe available today, while ensuring a

626   reasonable simulation of the flooded areas compared to the satellite-based estimates. For global

627   hydrological applications such a tuning is certainly not advisable because it should be done

628   with an accurate atmospheric forcing (especially precipitation) which is generally not the case

629   at the global scale. It also could hide some model deficiencies related to the non-representation

630   of irrigation, groundwater dynamics, lakes, large ponds, and wetlands. However for climate

631   studies and from a pragmatic point of view, this tuning could permit to represent the

632   floodplains and especially its related direct evaporation with a reasonable accuracy while the

633   spatio-temporal variations in precipitation are generally poorly represented.

634   6. **Conclusions**

635   This study describes the evaluation of the ISBA-TRIP flood model that will be used for

636   global hydrological and climate applications. It is evaluated over the globe using off-line

637   simulations at a 1° by 1° resolution driven by the 1986-2006 3-hourly atmospheric forcing

638   from Princeton University. The flood scheme accounts explicitly for the precipitation

639   interception by the floodplains, the direct evaporation from the free water surface and the

640   possible re-infiltration into the soil. The simulated river discharges are evaluated against 122 in

641 situ gauging measurements distributed all over the globe, while the simulated flooded areas are

642 compared to satellite-derived inundation estimates from Prigent et al. (2007) and an alternative

643 product using jointly the GLWD database of lakes, wetlands and floodplains (Lehner and Döll

644 2004) and the MIRCA2000 crop irrigation product (Portman et al. 2010).

645   The results suggest that the proposed simple flood scheme generally provides a

646 reasonable estimation of the spatio-temporal variability of flooded areas. In addition, the

647 simulated river discharges are improved by this scheme for the majority of the gauging stations

648 affected by floods. This positive impact is mainly related to: (1) an increase in evapo-

649 transpiration and then a decrease in river discharges especially relevant over the regions where

650 the simulated river discharges are overestimated without the flooding scheme; (2) the flood

651 scheme delay and attenuated river peak flow when the floodplain storage is significant. As far

652 as the annual mean water budget is concerned, this increase in evapotranspiration is

653 particularly important at a regional scale and is expected to have a significant regional impact

654 on global climate simulation.

655   Nevertheless, some deficiencies appear throughout the model evaluation. Different

656 reasons can account for such residual biases: uncertainties in the atmospheric forcing

657 (Chapelon et al. 2002; Fekete et al. 2003, Ngo-Duc et al. 2005; Decharme and Douville

658 2006b), possible anthropogenic influence on the observed discharges, and deficiencies in the

659 ISBA-TRIP model. Further improvements could be made by adding an explicit representation

660 of irrigation, lakes, marshes, and large ponds. Over high latitudes, the explicit simulation of the

661 permafrost could potentially improve the present results. In addition, the treatment of

662 groundwater in TRIP could be considerably improved by using a two dimensional approach

663 where the water flux between the groundwater and ISBA or the stream reservoir as well as the

664 water exchange between each neighboring grid-cell could be explicitly calculated (Fan et al.

30

665   2007; Miguez-Macho et al. 2007). In addition, satellite-derived inundation estimates could also

666   show some limitation as for example over South Asia, which exhibits very large inundation

667   extents throughout the year.

668   Besides these reasons, some aspects of the scheme are obviously questionable, such as

669   the empirical computation of the river width, the choice of the river bankfull height, the simple

670   computation of the river slope, the simplified geometry of the river stream and flood reservoirs,

671   or the use of the Manning's formula for computing the mass transfer between them. It must be

672   recognized that the most important parameter is the river width because it mainly controls the

673   good simulation of the river height and the river stream flow velocity (Equations 1 and 2).

674   With the river bankfull depth, it controls also the potential mass of water that can be flooded

675   (Equation 6). The accurate computation of the river slope and/or the value of the Manning's n

676   coefficient are secondary but could help to refine the ISBA-TRIP simulations. The choice of

677   these parameters in this study appear reasonable for this scheme that has been developed for

678   global climate applications, at a relatively low horizontal resolution (0.5° to 1° resolution), and

679   that must be as robust as possible to be applicable over all regions of the world. This first

680   attempt represents another step toward the representation of all inland water bodies in climate

681   simulations. Other limitations are the resolutions of the Digital Elevation Model (DEM) that

682   can induce an underestimation of the simulated flooded fraction through a failure to represent

683   very flat regions or areas smaller than the horizontal and vertical resolution of the DEM (Coe

684   1998, Coe et al. 2008).

685   Finally, the sensitivity experiments reveal the non-negligible impact of the river

686   bankfull height on the quality of the simulated flooded areas and river discharges. It also

687   impacts the intensity of the land surface evaporation increase. These results underline that the

688   river bankfull height is potentially tunable region by region. However, such a tuning must be

689   taken with caution on the global scale for at least two reasons:

690   (1) it might be sensitive to the experimental conditions and especially to the quality of the

691   prescribed atmospheric forcing which is less robust than at a regional scale;

692   (2) it could mask the model deficiencies related to the non-representation of irrigation,

693   groundwater dynamics, lakes, large ponds, and wetlands.

694   Another way could be suggested: the development of a global database describing the major

695   river characteristics as the stream width and the river bankfull height. Such a database would

696   be an important progress for future hydrological developments.

697

697 **APPENDIX A: The floodplain dynamics**

698   The flood inflow and outflow velocities computed using the Manning's formula

699 (Equation 7) requires the hydrological slope between the floodplain and the river stream:

700
$$\left| \begin{array}{l} s_{in} = \dfrac{max(0, h_s - h_c - h_f)}{(W + W_f)/2} \\[3mm] s_{out} = \dfrac{max(0, h_f + h_c - h_s)}{(W + W_f)/2} \end{array} \right.$$
(A1)

701 They also require the hydraulic radius assumed rectangular and calculated as follows:

702
$$\left| \begin{array}{l} R_{in} = \dfrac{L_f \times max(0, h_s - h_c)}{L_f + 2 \times max(0, h_s - h_c)} \\[3mm] R_{out} = \dfrac{L_f h_f}{L_f + 2 h_f} \end{array} \right.$$
(A2)

703 where W_f (m), L_f (m) and h_f (m) are the width, the length and the depth of the floodplains, h_s

704 (m) the water height of the stream reservoir, h_c (m) the critical height of the river bed, and W

705 (m) the stream river width.

706   h_f is calculated in each grid-cell with the help of the actual distribution of the local

707 height, h_i (m), determined at a 1 km by 1 km resolution. The assumption is that each pixel, i,

708 represents a sub-basin into a given grid-cell that can be potentially flooded as shown in Figure

709 14a. Each sub-basin has a triangular form and is associated with a fraction, f_i, of the grid cell

710 area, A. h_i is computed using the local slope, σ_i (°), and flow direction data given by the

711 HYDRO1K data set (Verdin and Greenlee 1996) at 1km resolution:

712     $h_i = l \sqrt{\alpha_i} \, tan\left(\sigma_i \dfrac{\pi}{180} \right)$ (A3)

713   where l (m) is the characteristic length of one pixel equal to 1000 m, and α_i is equal to 1 if the

714   local flow direction is north, south, east, or west, and to 2 elsewhere. Therefore, for each h_i a

715   potential mass of flood, $V(h_i)$ (kg), can be simply calculated using a discrete equation:

716    $$V(h_i) = \rho_w \sum_0^i V_i \quad \text{where} \quad V_i = \frac{Af_i h_i}{2} \tag{A4}$$

717   As shown in Figure 14b, the sub-grid distributions of the flooded fraction and the flood depth

718   allow to determine f_{flood}, and h_f at each time step and in each grid-cell via the comparison

719   between the water mass into the floodplain reservoir, F, computed by TRIP (Equation 4) and

720   the sub-grid distribution of this potential mass $V(h_i)$:

721    $$F = V(h_i) \Rightarrow \left| \begin{array}{l} f_{flood} = \sum_0^i f_i \\ h_f = h_i \end{array} \right. \tag{A5}$$

722   When f_{flood} is known within the grid cell, W_f and L_f are simply calculated as follow:

723    $$\left| \begin{array}{l} L_f = max\left(0.001, r\sqrt{f_{flood}A}\right) \\ W_f = \dfrac{Af_{flood}}{L_f} \end{array} \right. \tag{A6}$$

724   where r is the meandering ratio fixed to 1.4 as recommended by Oki and Sud (1998).

725   Finally, because ISBA uses a single surface temperature, a new fraction, p_{ff}, is added in

726   each grid cell to account for the effect of the floodplains on the surface energy budget. A

727   fraction of vegetation masked by the floodplains, $p_{f,veg}$, is estimated and combined with the

728   TRIP flooded fraction, f_{flood}, as follows to limits the floodplain evaporation under dense

729   canopy:

730    $$\left| \begin{array}{l} p_{f,veg} = f_{flood} \times min\left[1, \dfrac{3}{LAI}\right] \\ p_{ff} = (1-veg)f_{flood} + veg\ p_{f,veg} \end{array} \right. \tag{A7}$$

34

731   where *LAI* (m.m^{-1}) is the leaf area index given by the ECOCLIMAP data base and *veg* the

732   dimensionless fraction of the vegetation in each grid cell. According to the ECOCLIMAP

733   database, the LAI is generally inferior to 3 for low vegetation (e.g., grassland, crops) and

734   superior for high vegetation (e.g., trees, forests). Then, the direct evaporation (or sublimation if

735   the surface temperature is inferior to 0°C), E_f (Kg.m^{-2}), from this flooded fraction is simply

736   estimated by:

737   $$E_f = p_{ff} \rho_a C_H V_a [q_{sat}(T_s) - q_a] \tag{A8}$$

738   where ρ_a (kg.m^{-3}) is the air density, q_a (kg.kg^{-1}) the air humidity, V_a the wind speed (m.s^{-1}), C_H

739   the dimensionless drag coefficient depending upon the thermal stability of the atmosphere and

740   q_{sat} (kg.kg^{-1}) the saturated specific humidity at the surface that depends on surface temperature,

741   T_s (K).

TABLE CAPTIONS

TABLE 1 - Examples of river basin characteristics in the TRIP 1° by 1° network. The basin name, the basin drainage area (*Area* in km²), the locations (longitude, *Lon*, and latitude, *Lat*), the basin *β* coefficient (Equation 8), and the width (m) are given. The different values of the bankfull height at each river mouth are also shown.

Basins	Area (km²)	Lon	Lat	β	Width (m)	h_c (m)	h_c -25%	h_c +25%
Amazon	6 134 937	-50.5	0.5	32	14755	25	18.75	31.25
Congo	3 751 344	12.5	-5.5	32	6860	19	14.25	23.75
Mississippi	3 245 654	-90.5	29.5	15	2 112	13	9.75	16.25
Parana	3 007 044	-58.5	-34.5	20	2872	14	10.5	17.5

TABLE 2 - The 12 vegetation types specified according to the 1-km ECOCLIMAP data base and the corresponding floodplain roughness coefficient, n_i, used in Equation 10.

	Vegetation types	*Floodplain roughness coefficient*
1	Bare soil	0.035
2	Rocks	0.035
3	Permanent snow and ice	0.035
4	Forest and trees	0.075
5	Coniferous forest	0.100
6	Broadleaf evergreen forest	0.100
7	C3 crops	0.050
8	C4 crops	0.050
9	Irrigated crops	0.050
10	Grassland	0.050
11	Tropical grassland	0.075
12	Peat bogs and Irrigated grass	0.075

FIGURES AND CAPTIONS
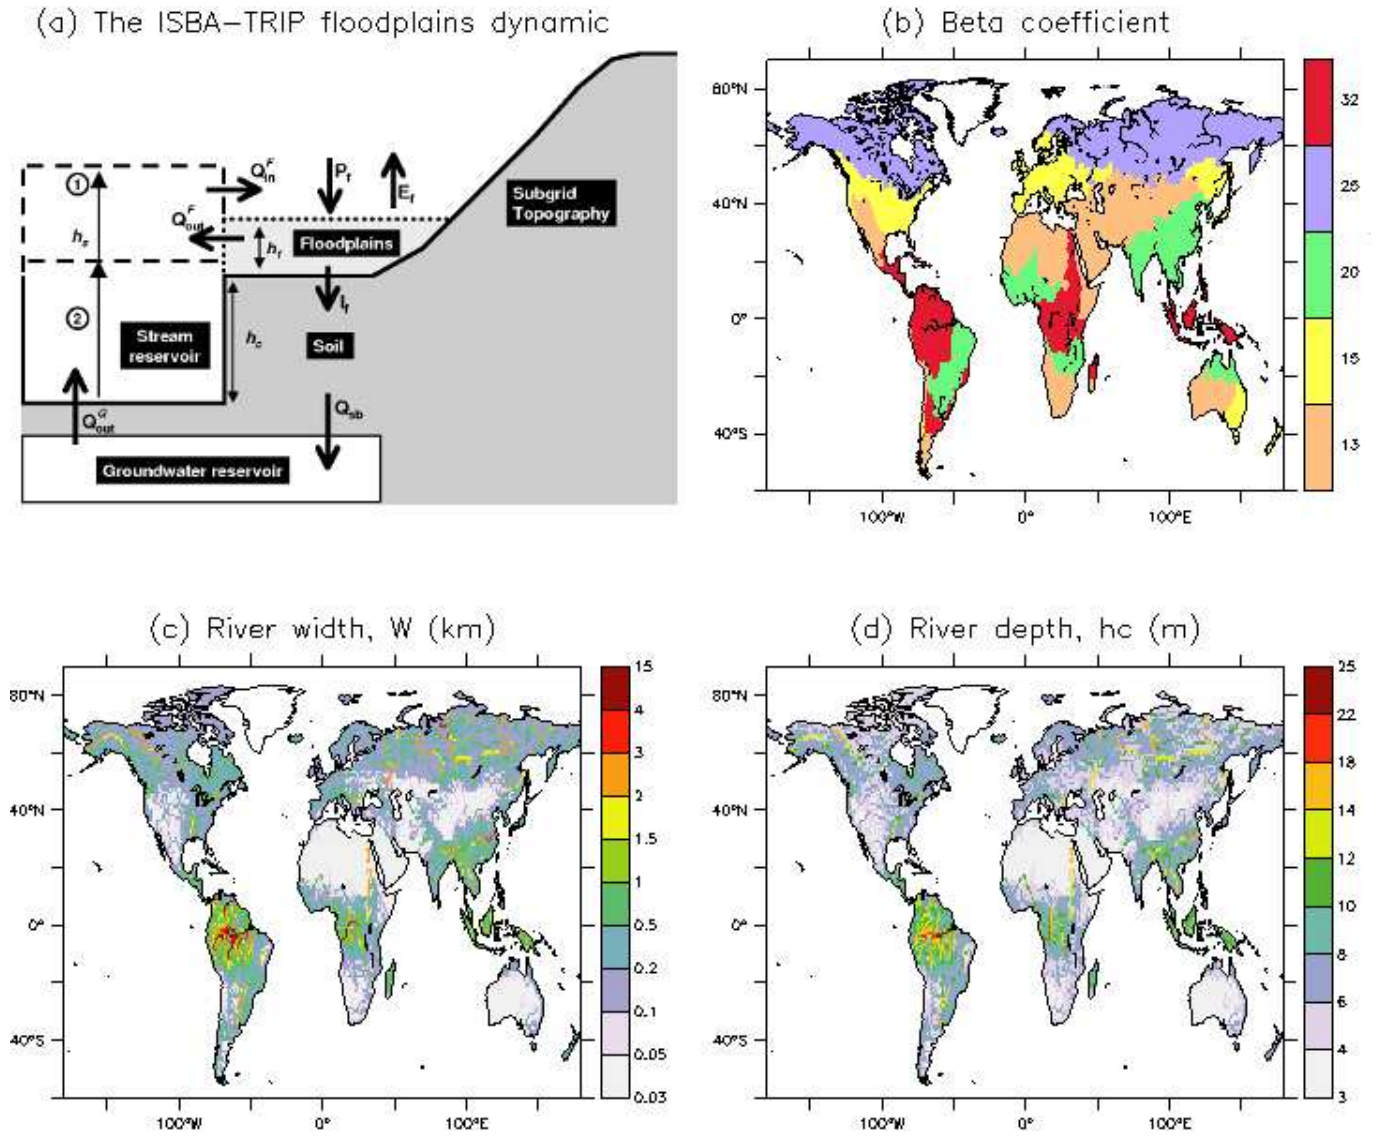

Figure 1 – The ISBA-TRIP floodplain dynamics and the Global distribution of its specific parameters. (a) Schematic representation: (case 1) when the river depth, h_s, is above the critical river bankfull height, h_c, a flood inflow, Q_{in}^F, is computed; (case 2) when the flood decreases, h_s becomes lower than the depth of the floodplains, h_f, and a flood outflow, Q_{out}^F, to the river is computed. See section 2 for more details. (b) The β coefficient used to compute the river width given in (c). (d) The bankfull river height. See section 3 for more details.
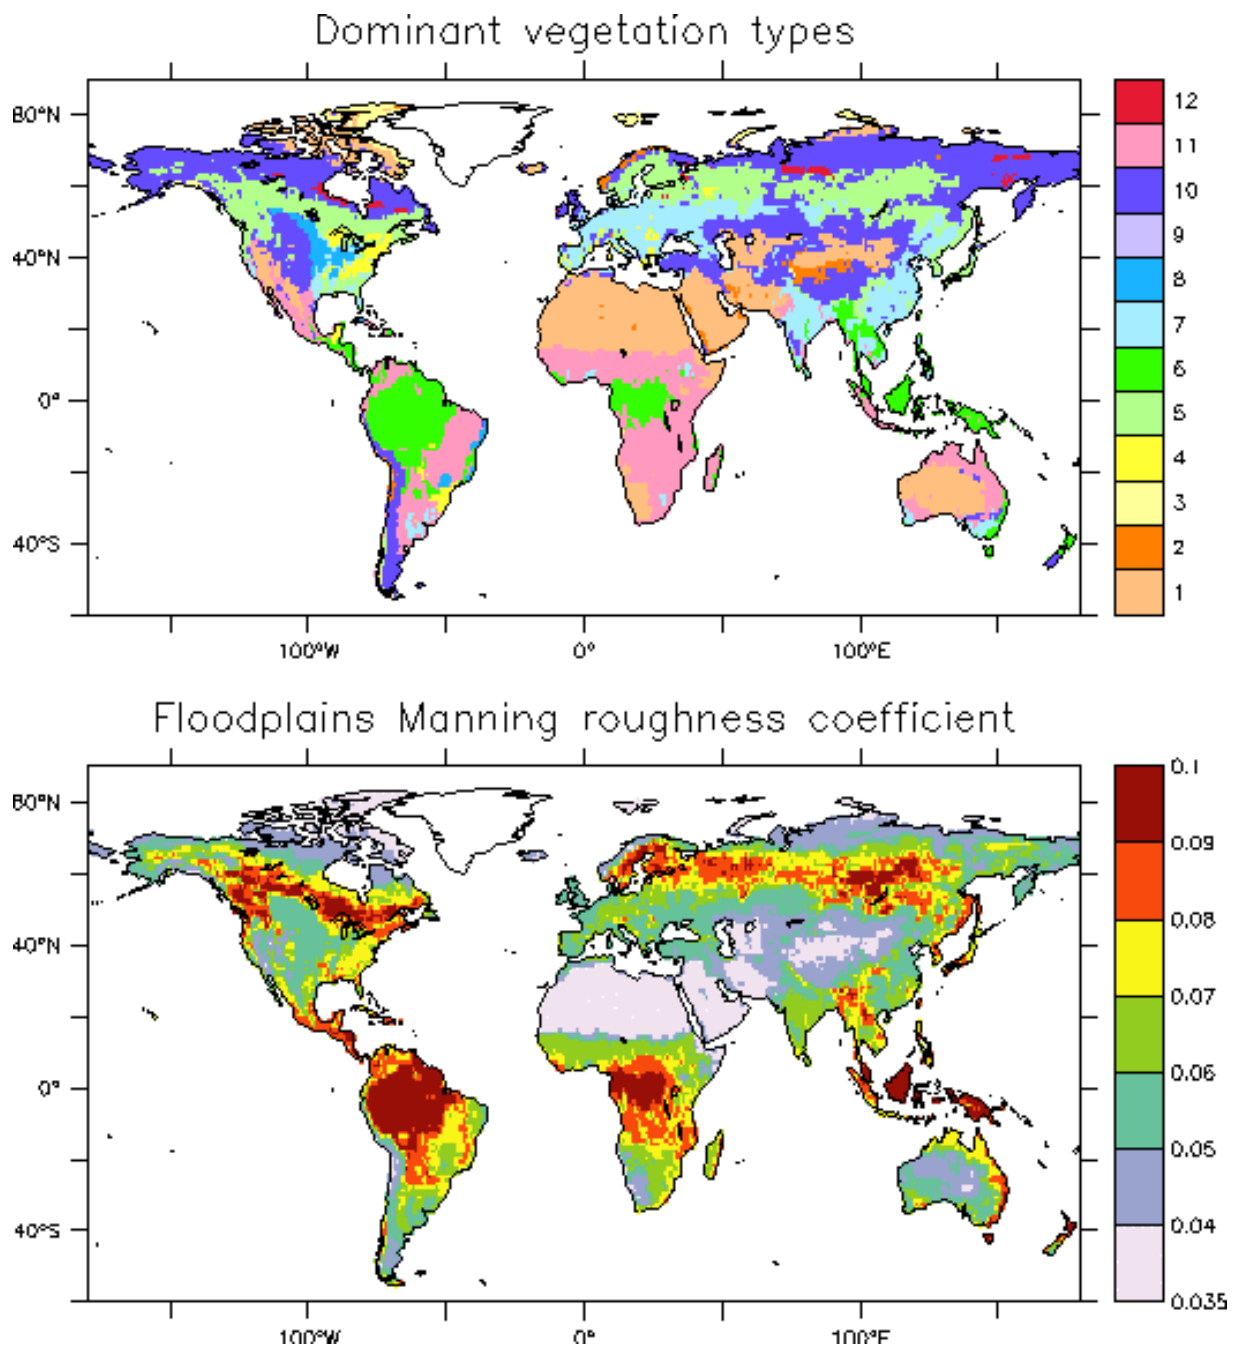

Figure 2 – Spatial distribution of the dominant vegetation types at 1° resolution specified according to the 1-km ECOCLIMAP data (top) and the associated floodplain Manning roughness coefficient (bottom). The 12 vegetation types are described in Table 2.
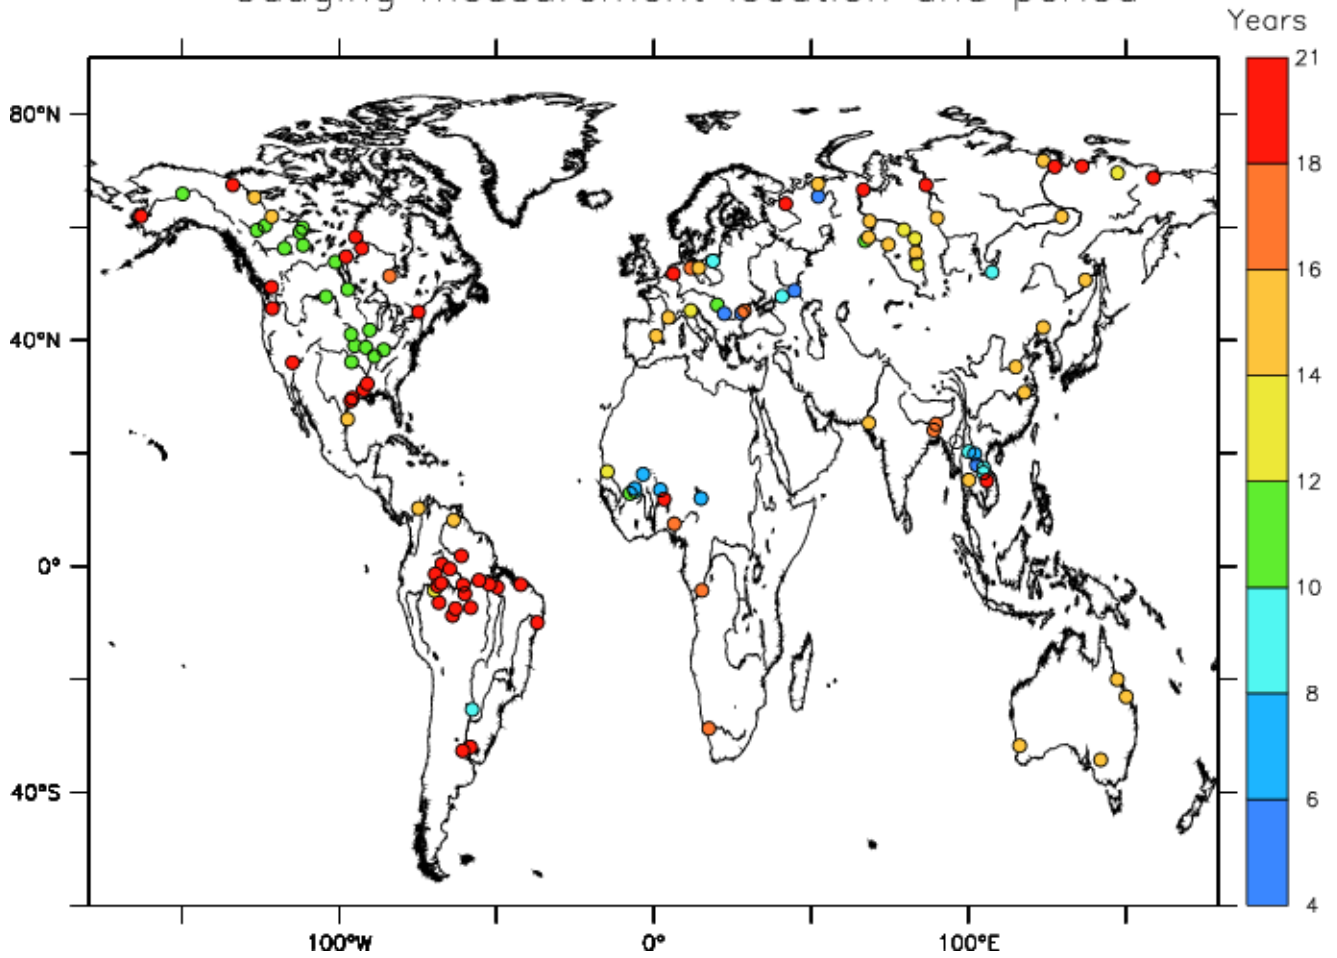

Figure 3 – Location of the 122 gauging stations used for the evaluation. The color on each station represents the number of year of monthly data available, beginning in January 1986.
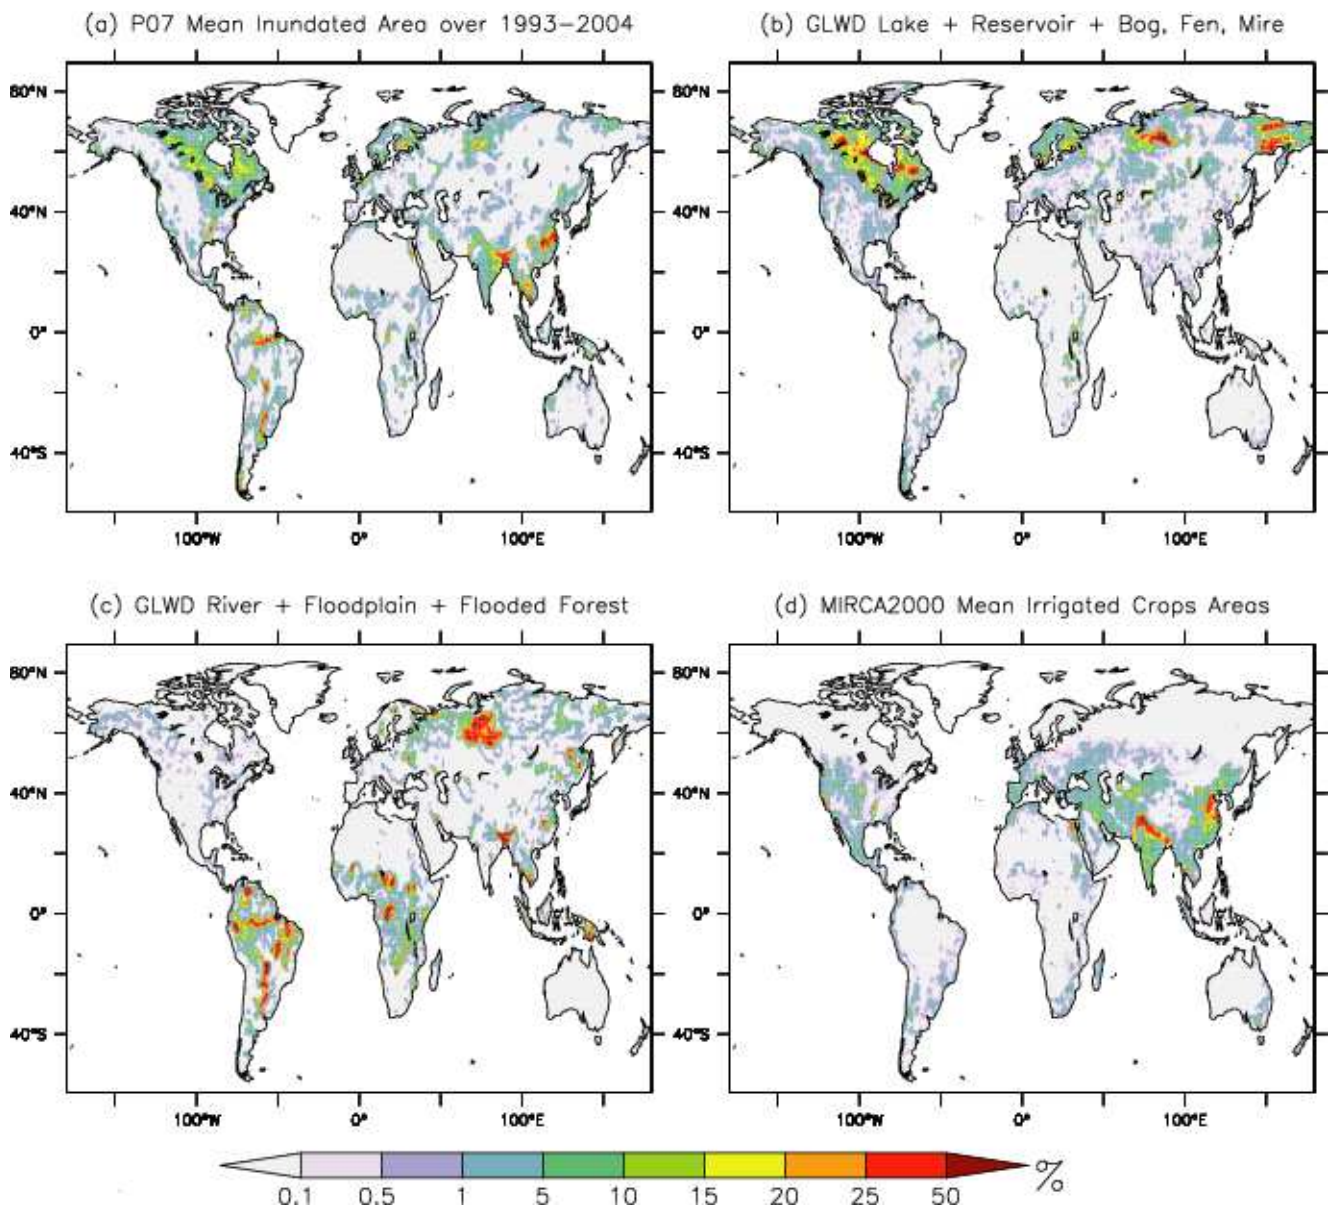

Figure 4 – The different data sets used for the floodplain evaluation. (a) The global distribution of the P07 1993-2004 mean inundated extent. (b) The lakes, reservoirs, bogs, fens and mires from the GLWD database. (c) The GLWD rivers, floodplains and flooded forest areas. (d) The MIRCA2000 mean irrigated crop extent.
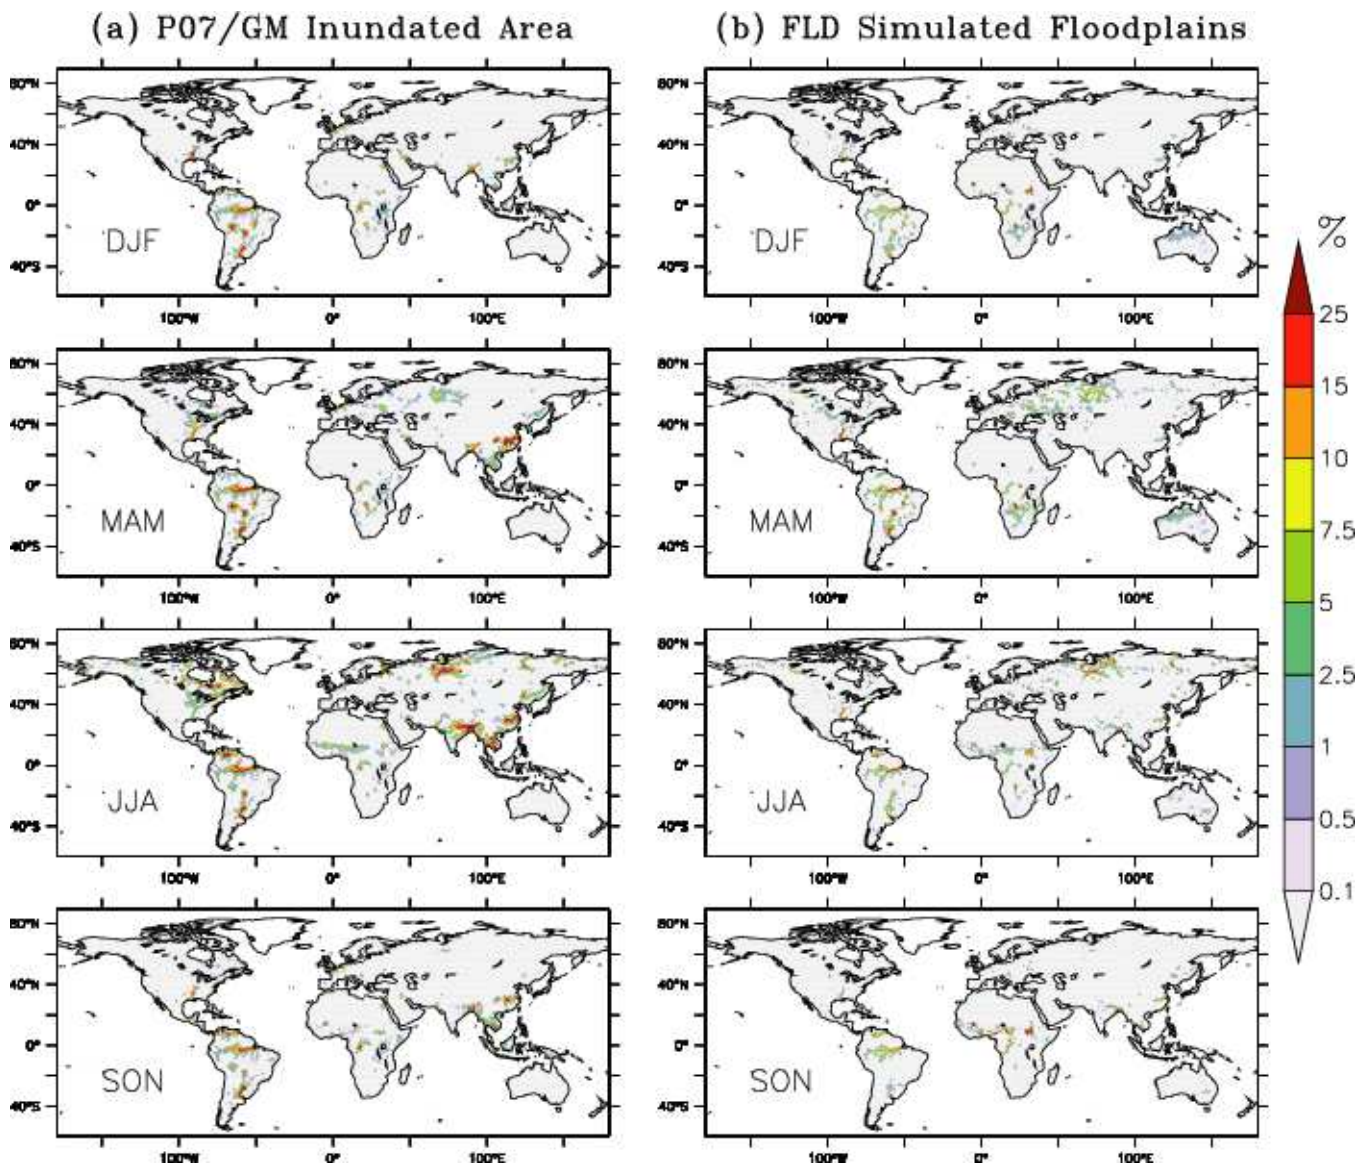

Figure 5 – Spatial distribution of the mean annual cycles of both the $P_{07/GM}$ inundated areas (b) and the simulated FLD floodplains.
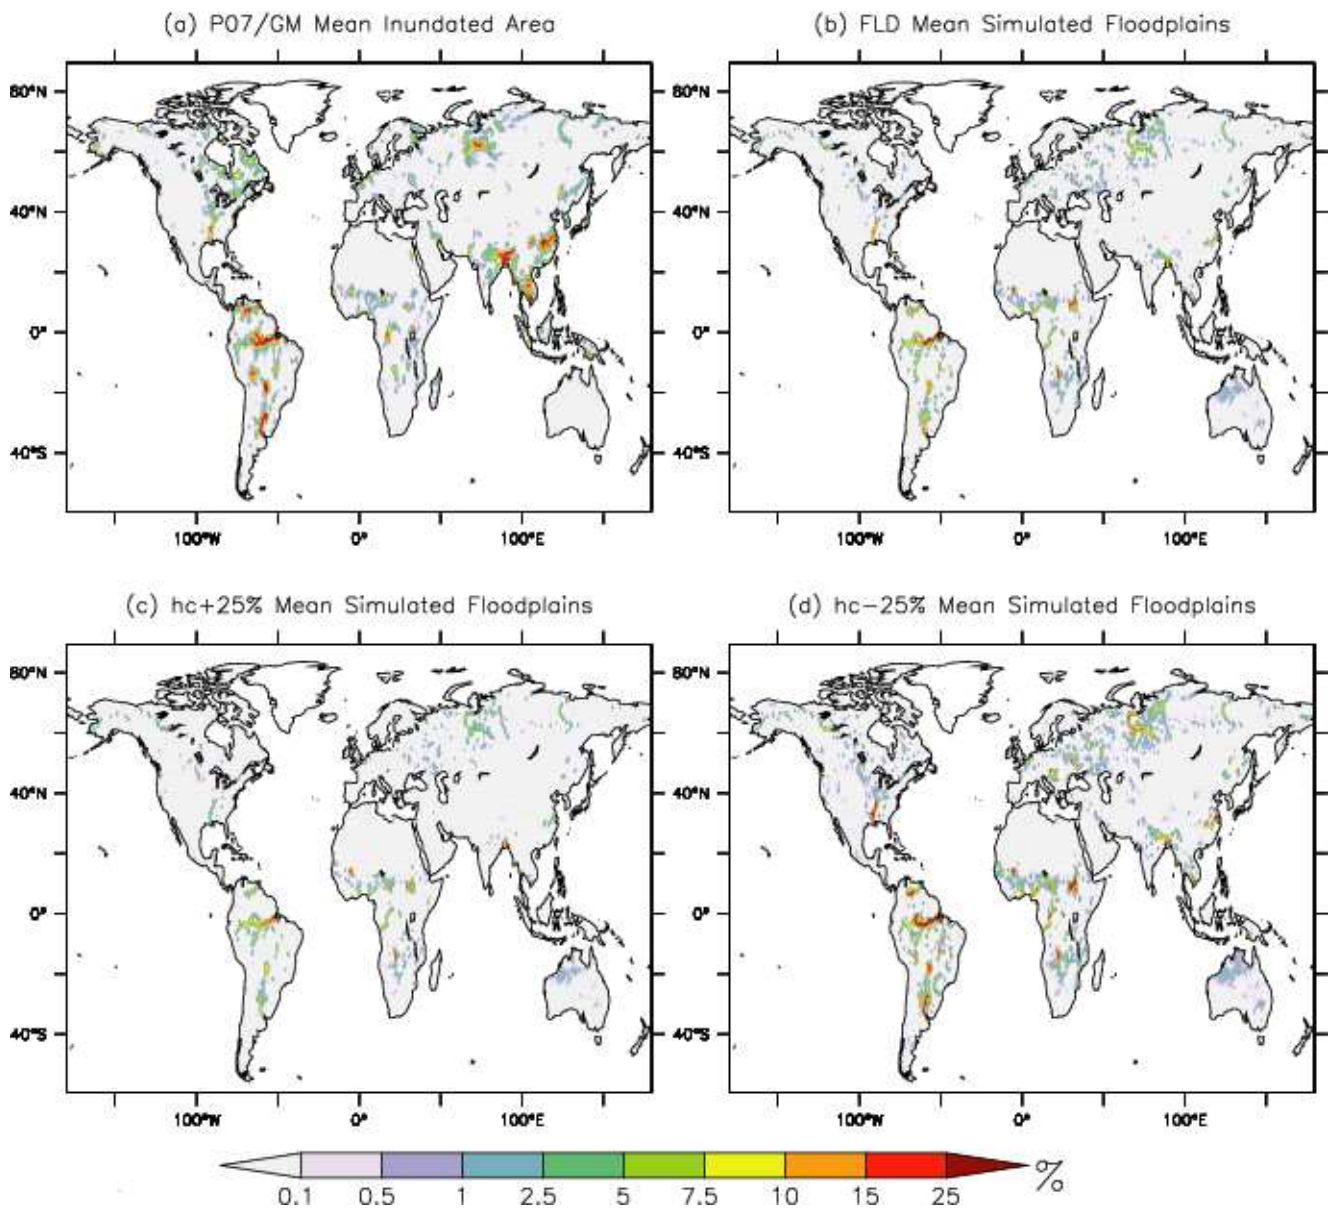

Figure 6 – Spatial distribution of the annual mean inundated areas estimated by $P_{07/GM}$ (a), simulated by FLD (b), and computed with $h_c \pm 25\%$ (c and d).
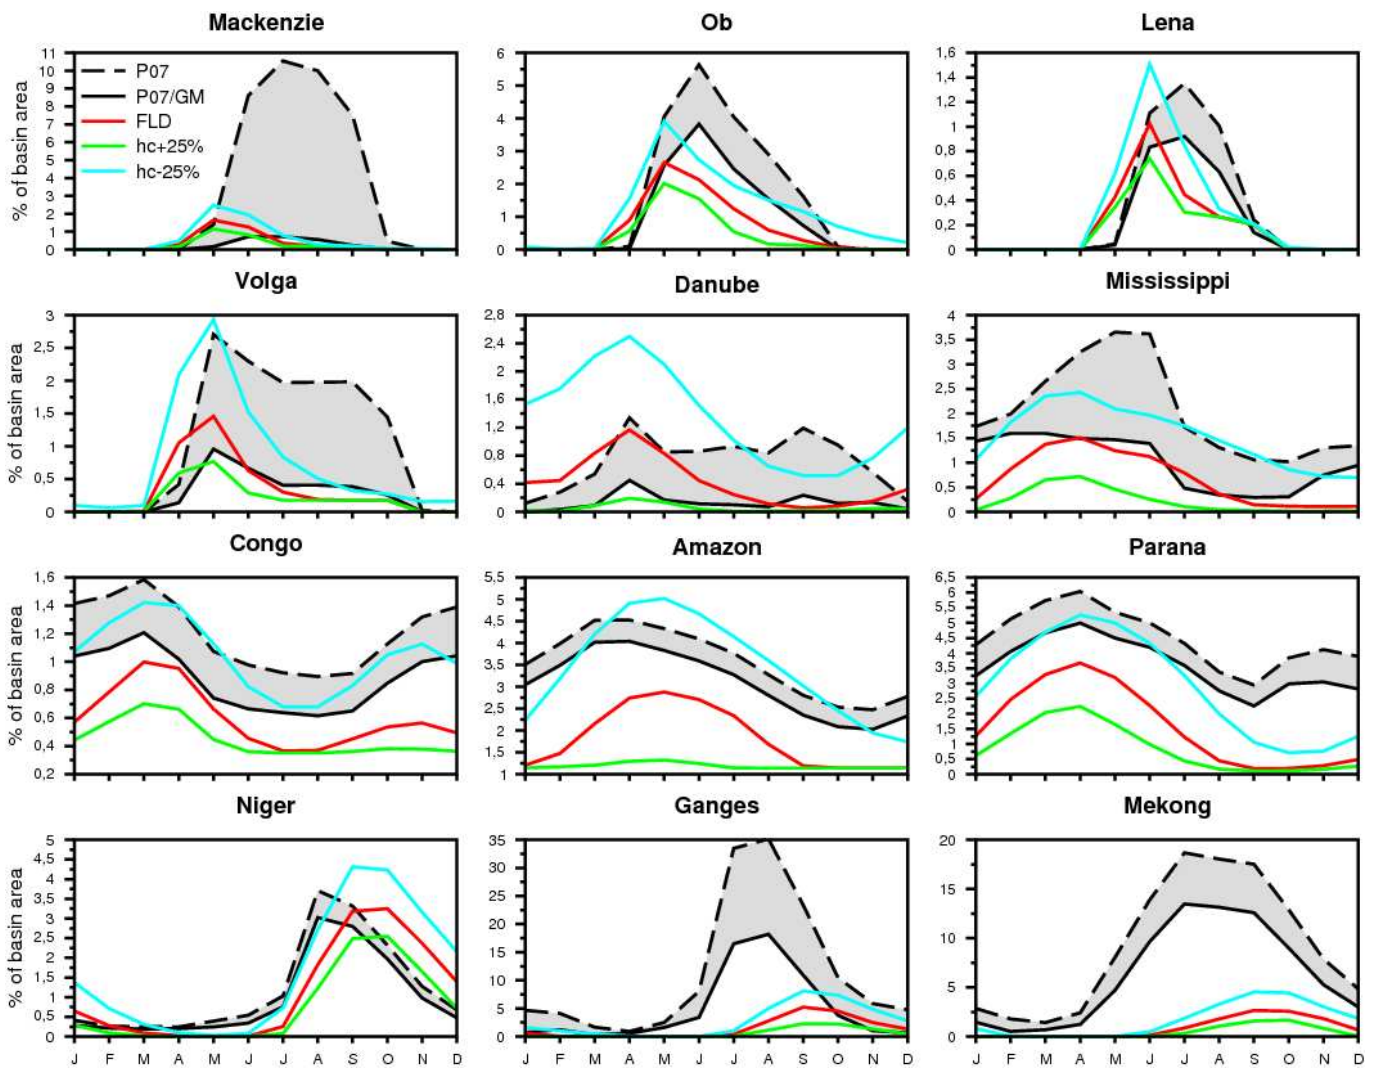

Figure 7 – Comparison over major river basins between the basin-averaged annual cycles of simulated and estimated flooded areas over the 1993-2004 period. P07 is in dashed black line, $P_{07/GM}$ in black, FLD in red, and $h_c\pm25\%$ in green and cyan. Note that the maximum value on the Y-axis is highly variable from one basin to the other.

54
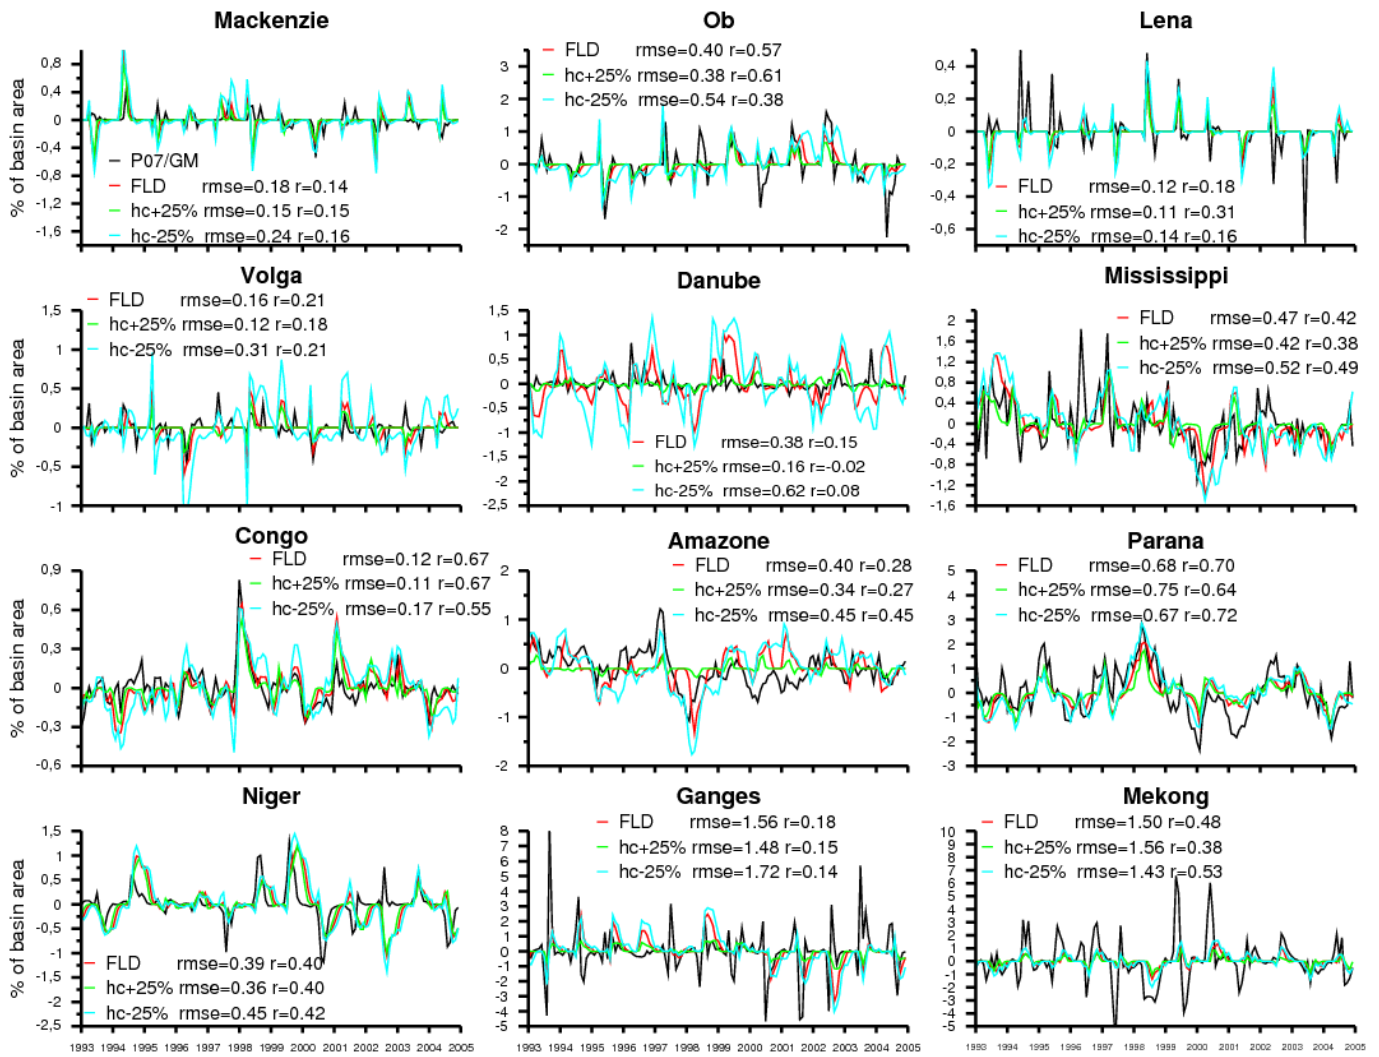

Figure 8 – Comparison between the major basin-averaged simulated and estimated (black line) floodplain anomalies over the 1993-2004 period. The Root Mean Square Error (RMSE) and the correlation (r) are given for each simulation. Notations are the same than in Figure 7.
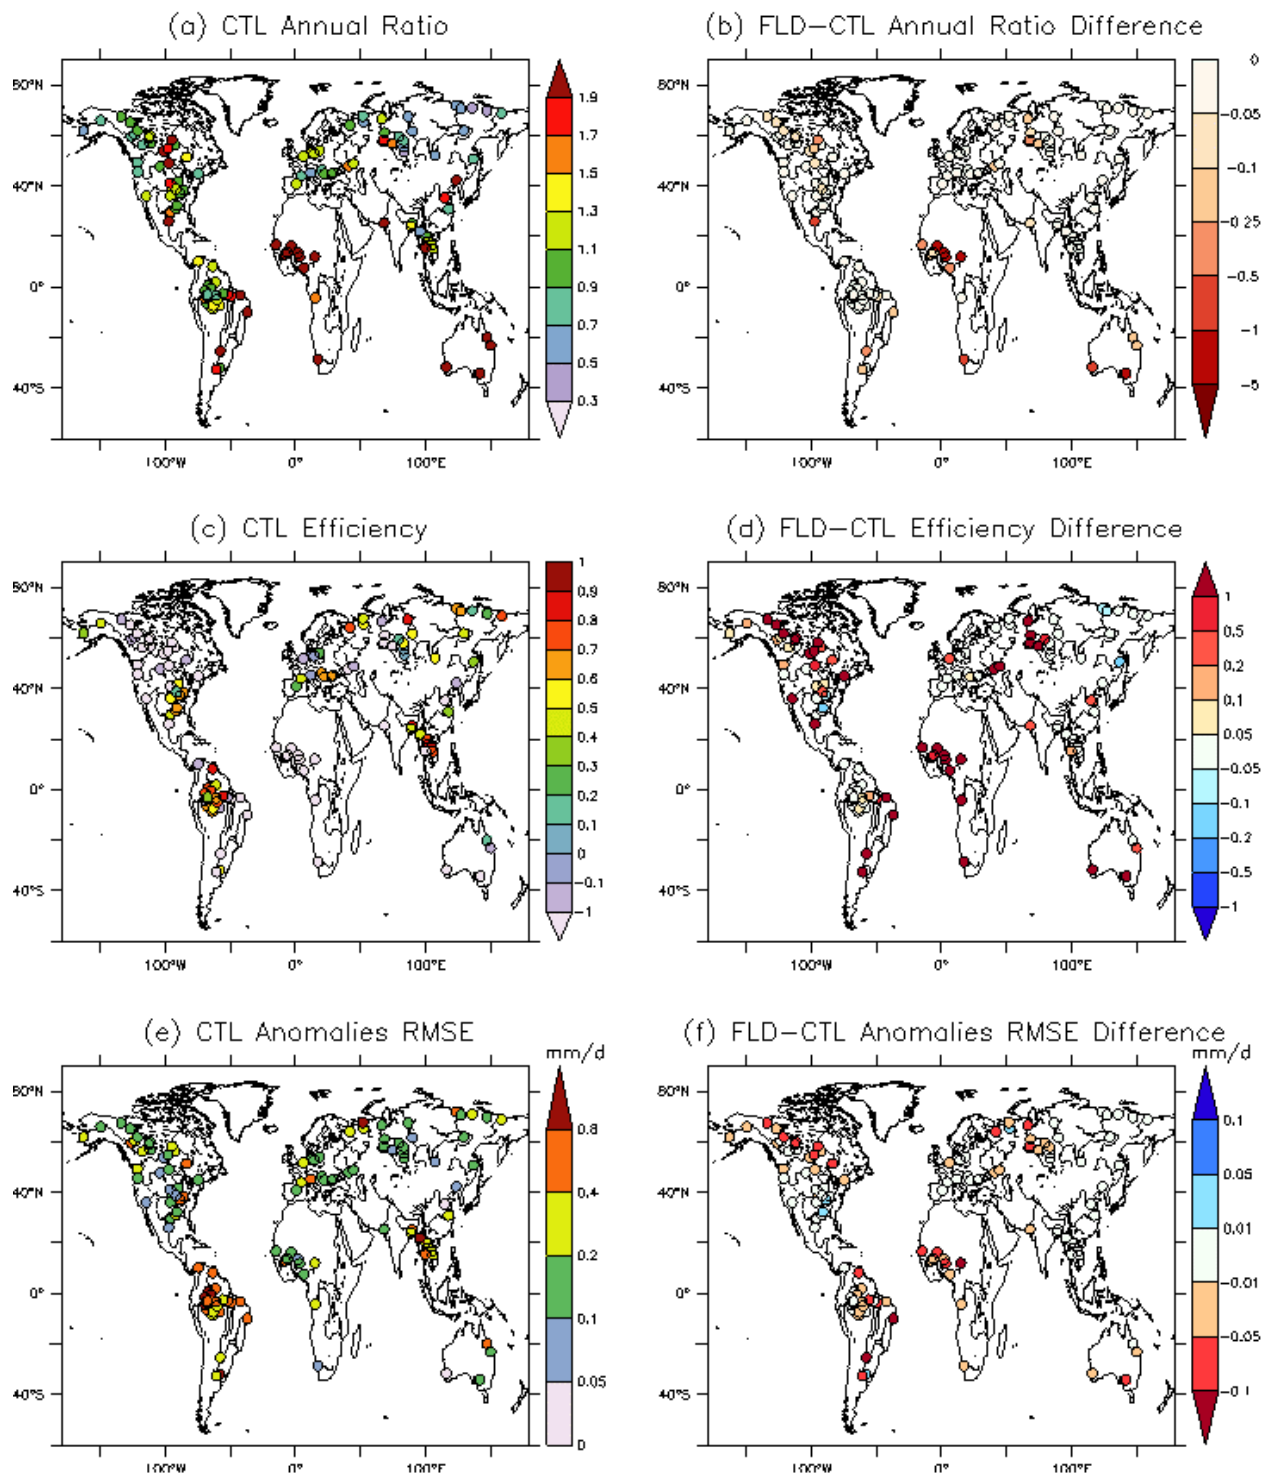

Figure 9 – Comparison between the simulated monthly discharge with (FLD) and without (CTL) the flood scheme at each 122 gauging station. The CTL annual ratio (a) and efficiency

(c) in terms of absolute values as well as the RMSE in terms of monthly anomalies (e) are given. The difference with the FLD scores is also shown (b, d, f).
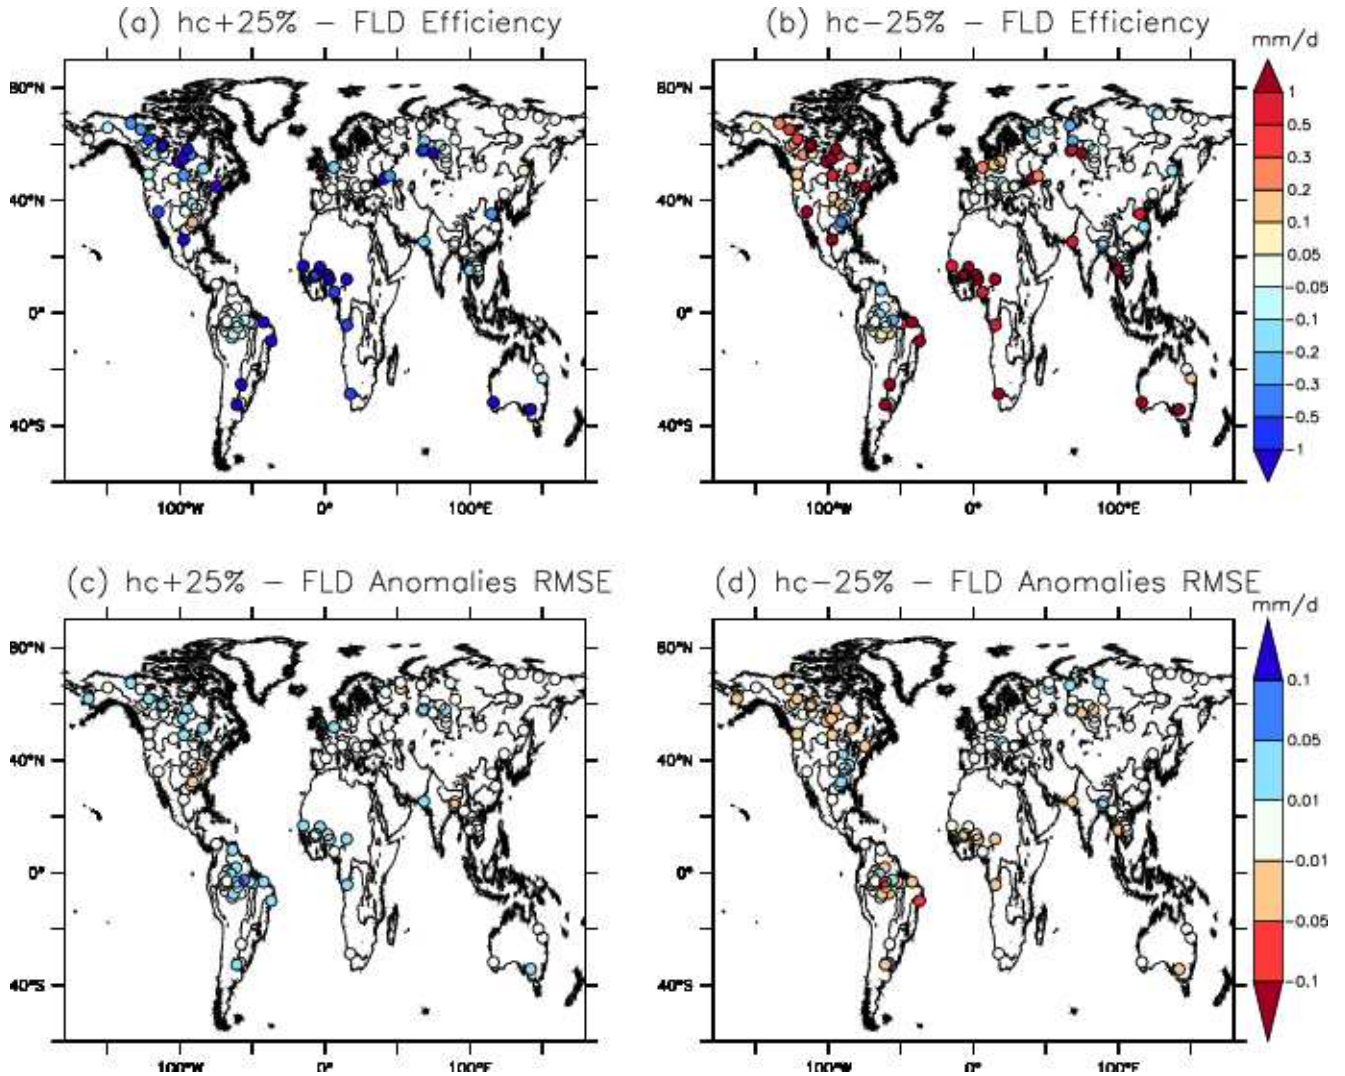

Figure 10 – Sensitivity of the simulated monthly discharge to the river bankfull height at each 122 gauging station. The difference between simulations with $h_c \pm 25\%$ and FLD is given in terms of efficiency (a, b), and monthly anomalies RMSE (c, d).
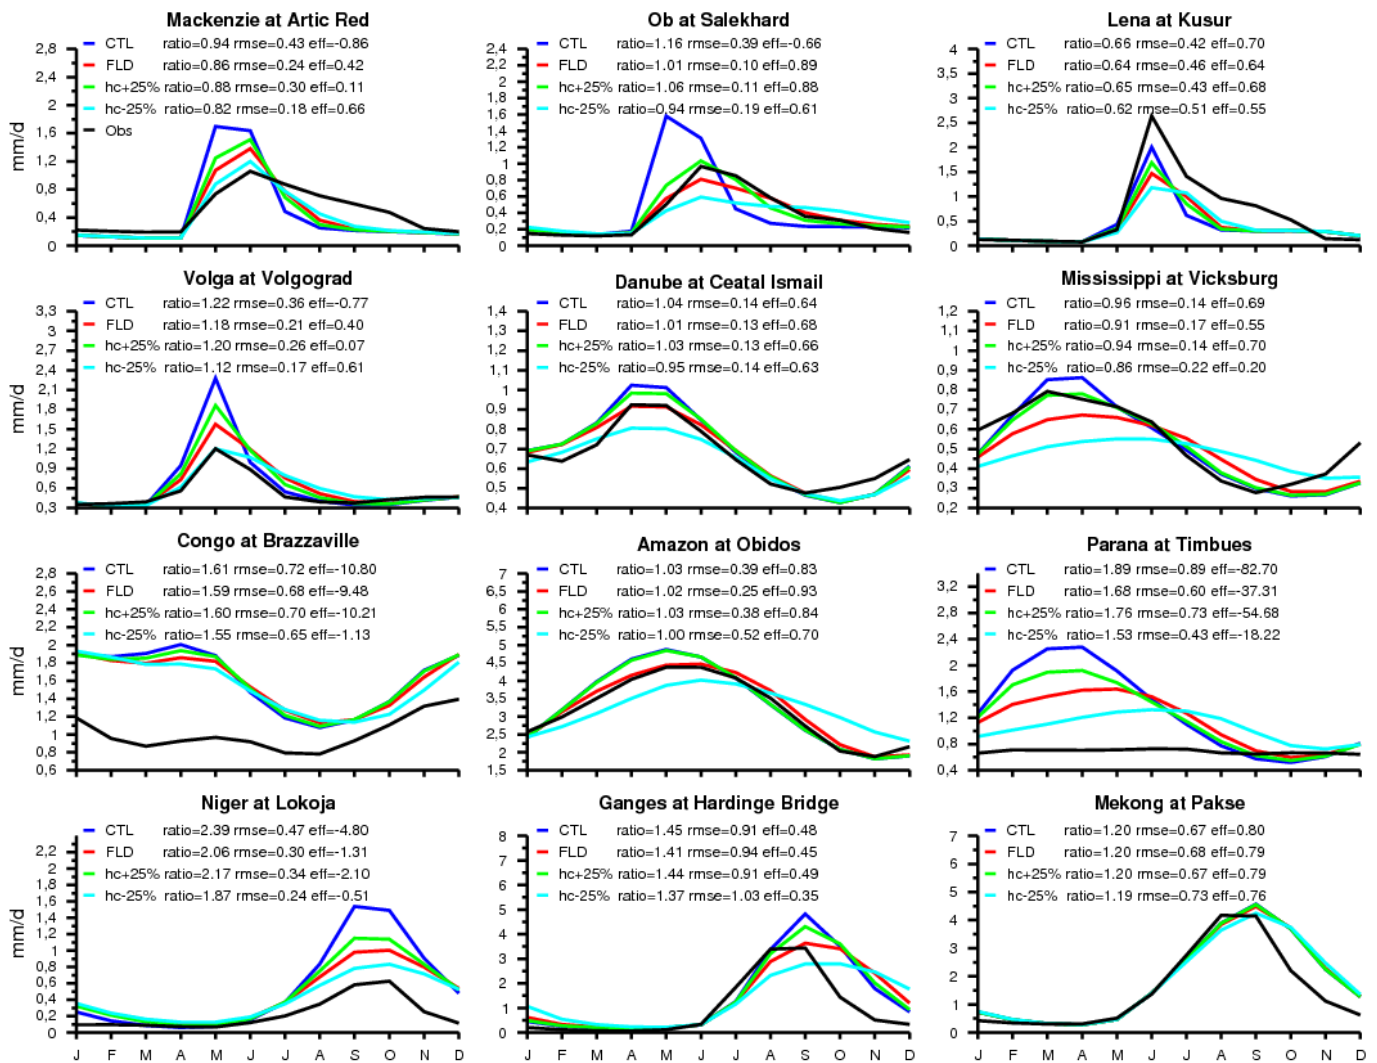

Figure 11 – Comparison between the mean annual cycles of simulated and observed (black line) discharges over the same basins than in Figure 7. Observations are in black line, CTL in blue, FLD in red, and $h_c \pm 25\%$ in green and cyan. The ratio, RMSE, and efficiency (eff) criteria given on each panel are calculated over the entire period and not over the annual cycle.
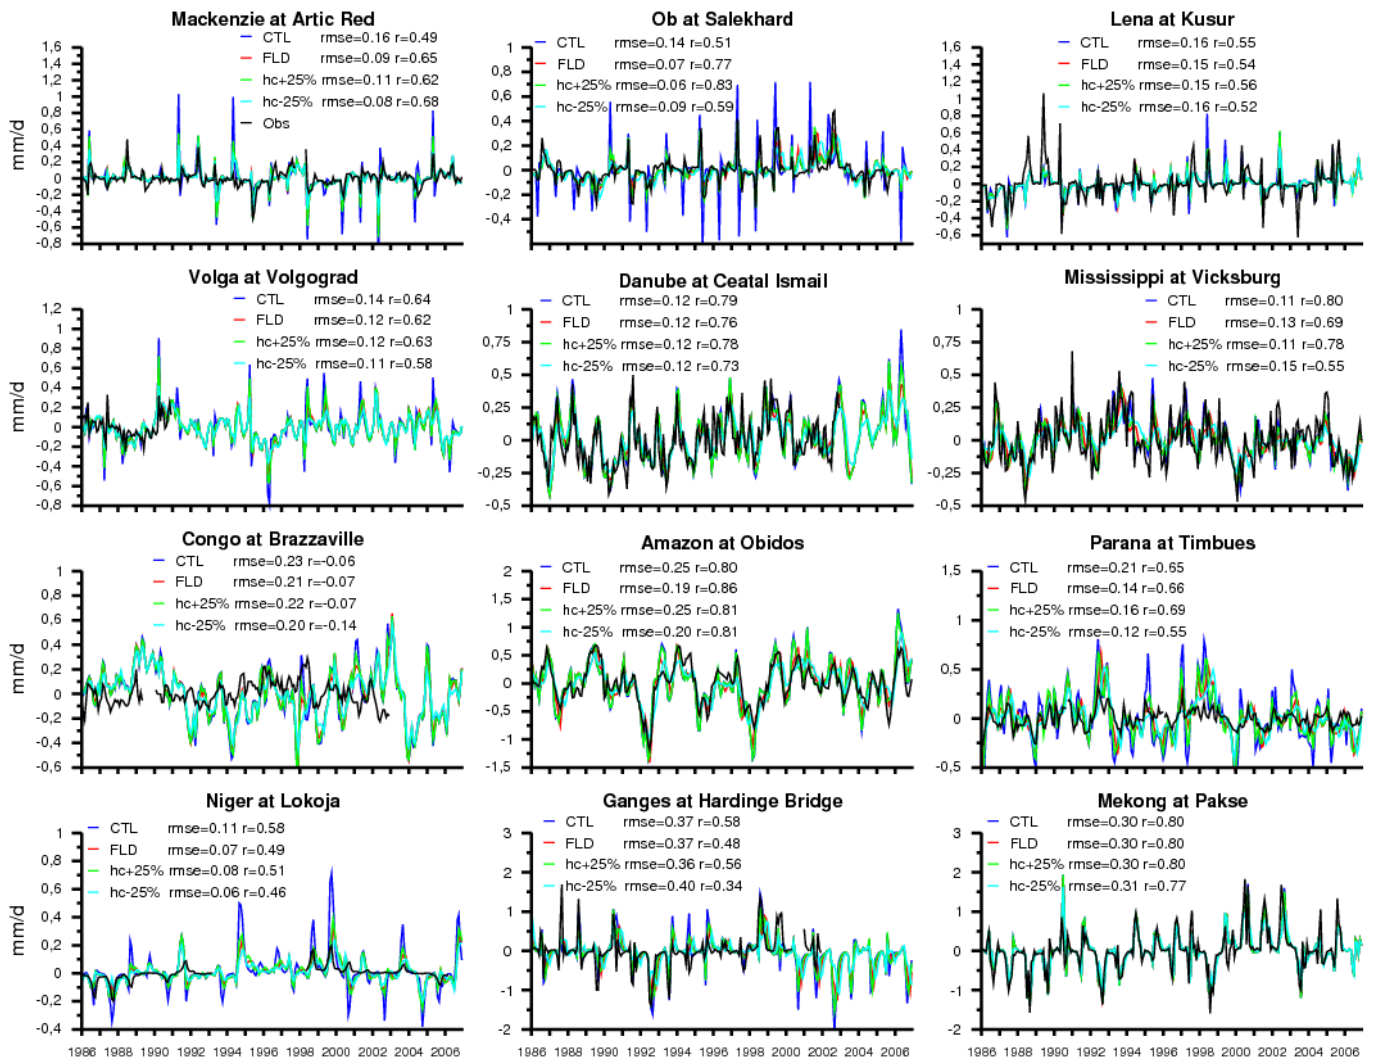

Figure 12 – Same as in Figure 10 but for the interannual variability. The RMSE and the correlation (r) are given for each experiment.
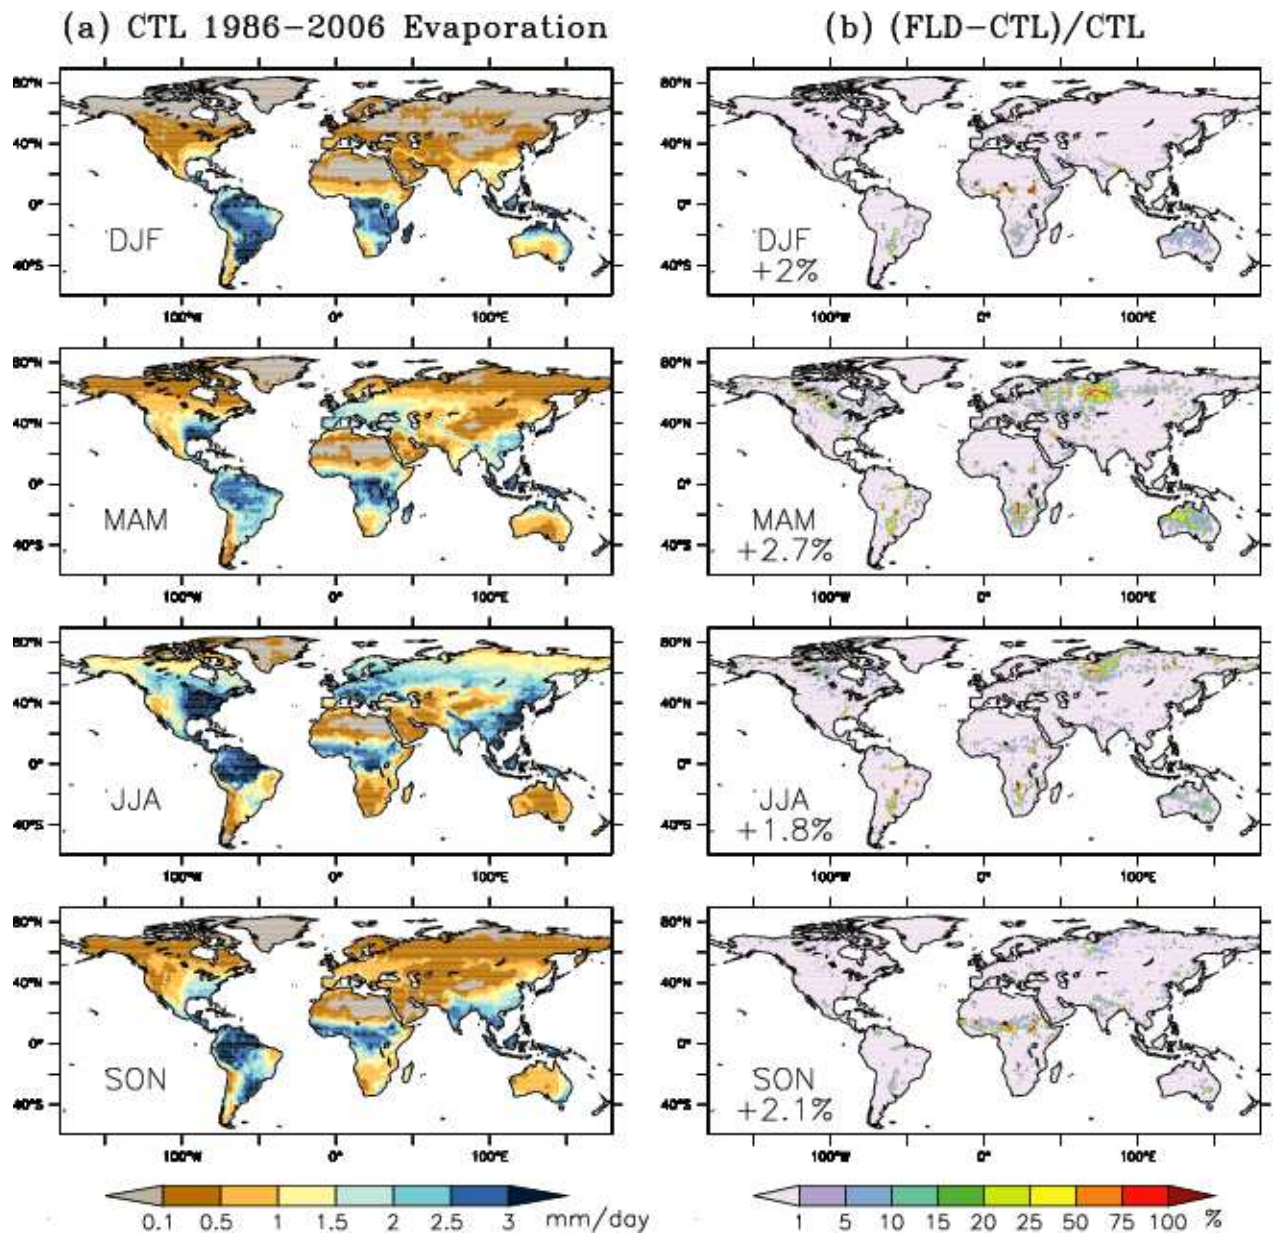

Figure 13 – Impact of the flood scheme on the evapotranspiration mean annual cycle computed by ISBA over the 1986-2006 period. (a) Global distribution of the CTL evapotranspiration. (b) Comparison in % between CTL and FLD.
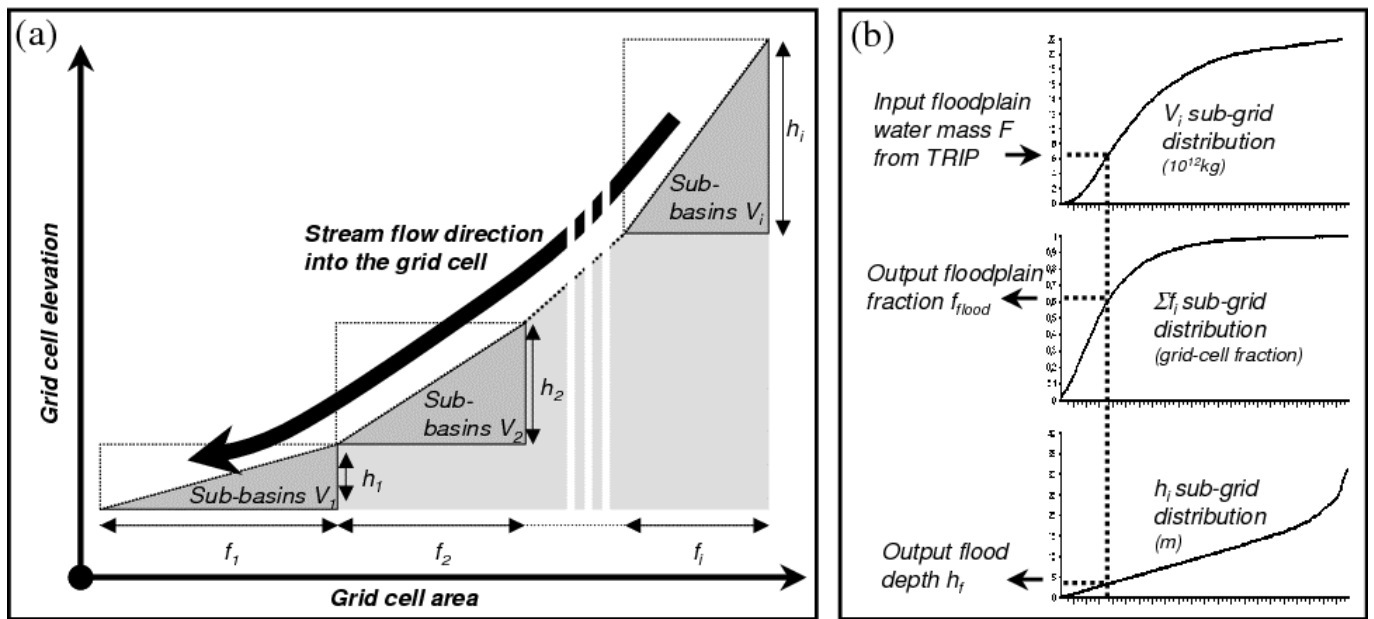

Figure 14 – Schematic representation of the floodplain sub-grid scheme. (a) One grid-cell is approximated as an individual basin where the water flows from the largest to the flattest slope of each pixel at 1 km resolution. Each pixel is then assumed as a sub-basin that can be potentially flooded. These pixels are ranked from the lower to the higher depth, h_i, computed according to the slope of each pixel. Then, a sub-grid area, f_i, and a potential water mass, V_i, can be associated with each entity. (b) The comparison of the floodplain water mass, F, computed by TRIP with the V_i sub-grid distribution permits to find the associated floodplain fraction, f_{flood}, and flood depth, h_f, into the grid cell via the sub-grid distribution of f_i and h_i respectively.
